called *early S-phase cyclins*. Inactivation of Cdh1 allows the S-phase cyclin-CDK complexes to accumulate in late G₁. The specificity factor Cdh1 is phosphorylated and inactivated by both late-G₁ and B-type cyclin-CDK complexes, and thus remains inhibited throughout S, G₂, and M phase until late anaphase when the Cdc14 phosphatase is activated and removes the inhibitory phosphate from Cdh1.

Degradation of the S-Phase Inhibitor Triggers DNA Replication

As the S-phase cyclin-CDK heterodimers accumulate in late G₁, they are immediately inactivated by binding of an inhibitor, called *Sic1*, that is expressed late in mitosis and in early G₁. Because *Sic1* specifically inhibits B-type cyclin-CDK complexes, but has no effect on the G₁ cyclin-CDK complexes, it functions as an *S-phase inhibitor*.

Entry into the S phase is defined by the initiation of DNA replication. In *S. cerevisiae* cells this occurs when the *Sic1* inhibitor is precipitously degraded following its polyubiquitination by the distinct ubiquitin-protein ligase called SCF mentioned earlier (Figure 20-28; see also Figure 20-2). Once *Sic1* is degraded, the S-phase cyclin-CDK complexes induce DNA replication by phosphorylating several proteins in prereplication complexes bound to replication origins. This mechanism for activating the S-phase cyclin-CDK complexes—that is, inhibiting them as the cyclins are synthesized and then precipitously degrading the inhibitor—permits the sudden activation of large numbers of complexes, as opposed to the gradual increase in kinase activity that would result if no inhibitor were present during synthesis of the S-phase cyclins.

We can now see that regulated proteasomal degradation directed by two ubiquitin-protein ligase complexes, SCF and APC/C, controls three major transitions in the cell cycle: onset of the S phase through degradation of *Sic1* by SCF, the beginning of anaphase through degradation of securin by the APC/C, and exit from mitosis through degradation of B-type cyclins by the APC/C. The APC/C is

▲ **FIGURE 20-28 Control of S phase onset in *S. cerevisiae* by regulated proteolysis of the S-phase inhibitor, Sic1.** The S-phase cyclin-CDK complexes (Clb5-CDK and Clb6-CDK) begin to accumulate in G₁, but are inhibited by Sic1. This inhibition prevents initiation of DNA replication until the cell is fully prepared. G₁ cyclin-CDK complexes assembled in late G₁ (Cln1-CDK and Cln2-CDK) phosphorylate Sic1 at

multiple sites (step **1**), marking it for polyubiquitination by the SCF ubiquitin ligase, and subsequent proteasomal degradation (step **2**). The active S-phase cyclin-CDK complexes then trigger initiation of DNA synthesis (step **3**) by phosphorylating components of pre-initiation complexes assembled on DNA replication origins in early G₁. [Adapted from R. W. King et al., 1996, *Science* **274**:1652.]

◀ **FIGURE 20-29 Activity of *S. cerevisiae* cyclin-CDK complexes through the course of the cell cycle.** The width of the colored bands is approximately proportional to the demonstrated or proposed protein kinase activity of the indicated cyclin-CDK complexes. *S. cerevisiae* produces a single cyclin-dependent kinase (CDK) whose activity is controlled by the various cyclins, which are expressed during different portions of the cell cycle.

directed to polyubiquitinate the anaphase inhibitor securin by the Cdc20 specificity factor (see Figure 20-23). The APC/C-Cdc20 complex also directs the degradation of S-phase cyclins and much of the mitotic cyclin, but sufficient mitotic cyclin remains to maintain chromosome condensation until late anaphase. Then, another specificity factor, Cdh1, targets the APC/C to the remaining B-type cyclins (see Figure 20-10).

In contrast to the APC/C, the SCF ubiquitin-protein ligase is not regulated by phosphorylation of specificity factors, but rather by phosphorylation of its substrate, Sic1. Sic1 is phosphorylated by G₁ cyclin-CDKs (see Figure 20-28). It must be phosphorylated at at least six sites, which are relatively poor substrates for the G₁ cyclin-CDKs, before it is bound sufficiently well by SCF to be polyubiquitinated. This difference in strategy for regulating the ubiquitin-protein ligase activities of SCF and APC/C probably occurs because the APC/C has several substrates, including securin and B-type cyclins, which must be degraded at different times in the cycle. In contrast, entry into the S phase requires the degradation of only a single protein, the Sic1 inhibitor. Also, the requirement for phosphorylating multiple weak sites in Sic1 delays the onset of S phase until G₁ cyclin-CDK activity has reached its peak and virtually all other G₁ cyclin-CDK substrates have been phosphorylated. An obvious advantage of proteolysis for controlling passage through these critical points in the cell cycle is that protein degradation is an irreversible process, ensuring that cells proceed irreversibly in one direction through the cycle.

Multiple Cyclins Regulate the Kinase Activity of *S. cerevisiae* CDK During Different Cell-Cycle Phases

As budding yeast cells progress through the S phase, they begin transcribing genes encoding two additional B-type

cyclins. These form heterodimeric late S-phase/early M-phase cyclin-CDK complexes that, together with the early S-phase cyclin-CDK complexes, activate DNA replication origins throughout S phase. The late S-phase/early M-phase cyclin-CDK complexes are named so because they also initiate formation of the mitotic spindle at the beginning of mitosis, with the help of two other mitotic cyclins. These additional mitotic cyclins are expressed when *S. cerevisiae* cells complete chromosome replication and enter G₂. They function as *late mitotic cyclins*, associating with the CDK to form complexes that mediate the events of mitosis.

Each group of cyclins thus directs the *S. cerevisiae* CDK to specific functions associated with various cell-cycle phases, as outlined in Figure 20-29. The mid-G₁ cyclin-CDK induces expression of late G₁ cyclins and other proteins in mid-G₁ by phosphorylating and activating the SBF and MBF transcription factors. The G₁ cyclin-CDKs inhibit the APC/C, allowing B-type cyclins (S-phase and M-phase cyclins) to accumulate; the G₁ cyclin-CDKs also activate degradation of the S-phase inhibitor Sic1. The early S-phase cyclin-CDK complexes then trigger DNA synthesis. The late S-phase cyclins also function as mitotic cyclins by triggering formation of mitotic spindles. The remaining two *S. cerevisiae* cyclins are mitotic cyclins whose concentrations peak midway through mitosis. They are also involved in mitotic spindle formation, but they mainly function as mitotic cyclins, forming complexes with CDK that trigger chromosome segregation and nuclear division (see Table 20-1).

Replication at Each Origin Is Initiated Only Once During the Cell Cycle

As discussed in Chapter 4, eukaryotic chromosomes are replicated from multiple **replication origins**. Initiation of replication from these origins occurs throughout S phase.

However, no eukaryotic origin initiates more than once per S phase. Moreover, the S phase continues until replication from multiple origins along the length of each chromosome results in complete replication of the entire chromosome. These two factors ensure that the correct gene copy number is maintained as cells proliferate.

Yeast replication origins contain an 11-base-pair conserved core sequence to which is bound a hexameric protein, the *origin-recognition complex (ORC)*, required for initiation of DNA synthesis. DNase I footprinting analysis (Figure 7-17) and immunoprecipitation of chromatin proteins cross-linked to specific DNA sequences (Figure 7-37) during various phases of the cell cycle indicate that the ORC remains associated with origins during all phases of the cycle. Several additional replication initiation factors required to initiate

DNA synthesis at origins were identified in genetic studies in *S. cerevisiae*. These DNA replication initiation factors associate with the ORC at origins during G₁, but not during G₂ or M. During G₁ the various initiation factors assemble with the ORC into a *prereplication complex* at each origin (Figure 20-30).

The restriction of origin “firing” to once and only once per cell cycle in *S. cerevisiae* is enforced by the alternating cycle of B-type cyclin-CDK activity levels through the cell cycle: low in telophase through G₁ and high in S, G₂, and M through anaphase (see Figure 20-29). As we just discussed, S-phase cyclin-CDK complexes become active at the beginning of S phase when their specific inhibitor, Sic1, is degraded. The prereplication complexes assembled at origins early in G₁ (Figure 20-30, step 1) initiate DNA synthesis in

◀ **FIGURE 20-30 Assembly and regulation of prereplication complexes.** Step 1: During early G₁, unphosphorylated replication initiation factors assemble on an origin-recognition complex (ORC) bound to a replication origin to generate a prereplication complex. Step 2: In the S phase, S-phase cyclin-CDK complexes and DDK phosphorylate components of the prereplication complex. Step 3: This leads to binding of Cdc45, activation of the hexameric MCM helicases, which unwind the parental DNA strands, and release of the phosphorylated Cdc6 and Cdt1 initiation factors. RPA binds to the resulting single-stranded DNA. Step 4: Initiation of synthesis by the DNA polymerase α-primase (see Figure 4-31). Step 5: Other components necessary for replication fork movement are recruited, and bidirectional synthesis away from the origin continues at each fork. ORC binds to the origin sequence in the daughter double-stranded DNA, but the phosphorylated initiation factors cannot assemble a prereplication complex on it. B-type cyclin-CDK complexes maintain the initiation factors in a phosphorylated state throughout the remainder of S, G₂, and early anaphase (top). These factors cannot assemble into new prereplication complexes until they are dephosphorylated by Cdc14 phosphatase and B-type cyclins are degraded following their polyubiquitination by the APC/C in late anaphase. Several additional factors required for replication are not shown.

S phase when they are phosphorylated by the S-phase cyclin-CDKs and a second heterodimeric protein kinase, DDK, expressed in G_1 along with other proteins involved in DNA replication (step 2). Although the complete set of proteins that must be phosphorylated to activate initiation of DNA synthesis has not yet been determined, there is evidence that phosphorylation of at least one subunit of the hexameric *MCM helicase* and of another initiation factor called *Cdc6* is required. Following their phosphorylation, the helicase unwinds the DNA, and the resulting single-stranded DNA is bound by the single-stranded binding protein RPA and other replication factors (Figure 20-30 steps 3, 4, and 5; see also Figure 4-31).

As the replication forks progress away from each origin, the phosphorylated initiation factors are displaced from the chromatin. However, ORC complexes immediately bind to the origin sequence in the replicated daughter duplex DNAs and remain bound throughout the cell cycle (see Figure 20-30, step 5). Origins can fire only once during the S phase because the phosphorylated initiation factors cannot reassemble into a prereplication complex. Consequently, phosphorylation of components of the prereplication complex by S-phase cyclin-CDK complexes and the DDK complex simultaneously activates initiation of DNA replication at an origin and inhibits re-initiation of replication at that origin. As we have noted, B-type cyclin-CDK complexes remain active throughout the S phase, G_2 , and early anaphase, maintaining the phosphorylated state of the replication initiation factors that prevents the assembly of new prereplication complexes (step 1).

When the *Cdc14* phosphatase is activated in late anaphase and the APC/C-Cdh1 complex triggers degradation of all B-type cyclins in telophase, phosphates on the initiation factors are removed by the unopposed *Cdc14* phosphatase. This allows the reassembly of prereplication complexes during early G_1 . As discussed previously, the inhibition of APC/C activity in G_1 sets the stage for accumulation of the S-phase cyclins needed for onset of the next S phase. This regulatory mechanism has two consequences: (1) prereplication complexes are assembled only during G_1 , when the activity of B-type cyclin-CDK complexes is low, and (2) each origin initiates replication one time only during the S phase, when S phase cyclin-CDK complex activity is high. As a result, chromosomal DNA is replicated only one time each cell cycle.

KEY CONCEPTS OF SECTION 20.5

Cyclin-CDK and Ubiquitin-Protein Ligase Control of S phase

- *S. cerevisiae* expresses a single cyclin-dependent protein kinase (CDK), which interacts with several different cyclins during different phases of the cell cycle (see Figure 20-29).
- Three G_1 cyclins are active in G_1 . The concentration of the mid- G_1 cyclin mRNA does not vary significantly through the cell cycle, but its translation is regulated by the availability of nutrients.

- Once active mid- G_1 cyclin-CDK complexes accumulate in mid-late G_1 , they phosphorylate and activate two transcription factors that stimulate expression of the late- G_1 cyclins, as well as enzymes and other proteins required for DNA replication, and the early S-phase B-type cyclins.
- The late- G_1 cyclin-CDK complexes phosphorylate and inhibit Cdh1, the specificity factor that directs the anaphase-promoting complex (APC/C) to B-type cyclins, thus permitting accumulation of S-phase B-type cyclins in late G_1 .
- S-phase cyclin-CDK complexes initially are inhibited by Sic1. Polyubiquitination of Sic1 by the SCF ubiquitin-protein ligase marks Sic1 for proteasomal degradation, releasing activated S-phase cyclin-CDK complexes that trigger onset of the S phase (see Figure 20-28).
- Late S-phase/early M-phase B-type cyclins, expressed later in the S phase, form heterodimers with the CDK that also promote DNA replication and initiate spindle formation early in mitosis.
- Late M-phase B-type cyclins, expressed in G_2 , form heterodimers with the CDK that stimulate mitotic events.
- In late anaphase, the specificity factor Cdh1 is activated by dephosphorylation and then directs APC/C to polyubiquitinate all the B-type cyclins. Their subsequent proteasomal degradation inactivates MPF activity, permitting exit from mitosis (see Figure 20-10).
- DNA replication is initiated from prereplication complexes assembled at origins during early G_1 . S-phase cyclin-CDK complexes simultaneously trigger initiation from prereplication complexes and inhibit assembly of new prereplication complexes by phosphorylating components of the prereplication complex (see Figure 20-30).
- Initiation of DNA replication occurs at each origin, but only once, until a cell proceeds through anaphase, when activation of APC/C leads to the degradation of B-type cyclins. The block on re-initiation of DNA replication until replicated chromosomes have segregated assures that daughter cells contain the proper number of chromosomes per cell.

20.6 Cell-Cycle Control in Mammalian Cells

In multicellular organisms, precise control of the cell cycle during development and growth is critical for determining the size and shape of each tissue. Cell replication is controlled by a complex network of signaling pathways that integrate extracellular signals about the identity and numbers of neighboring cells and intracellular cues about cell size and developmental program (Chapters 21 and 22). Most differentiated cells withdraw from the cell cycle during G_1 , entering the G_0 state (see Figure 20-1). Some differentiated cells (e.g., fibroblasts and lymphocytes) can be stimulated to reenter the cycle and replicate. Many postmitotic

▲ EXPERIMENTAL FIGURE 20-31 Microinjection experiments with anti-cyclin D antibody demonstrate that cyclin D is required for passage through the restriction point. The G_0 -arrested mammalian cells used in these experiments pass the restriction point 14–16 hours after addition of growth factors and enter the S phase 6–8 hours later. (a) Outline of experimental protocol. At various times 10–16 hours after addition of growth factors (1), some cells were microinjected with rabbit antibodies against cyclin D (2). Bromodeoxyuridine (BrdU), a thymidine analog, was then added to the medium (3), and the uninjected control cells (left) and microinjected experimental cells (right) were incubated for an additional 16 hours. Each sample was then analyzed to determine the percentage of cells that had incorporated BrdU into newly synthesized DNA (4), indicating that they had entered the S phase. (b) Analysis of control cells and experimental cells injected with anti-cyclin D antibody 8 hours after addition of growth factors. The three micrographs show the same field of cells stained 16 hours after

addition of BrdU to the medium. Cells were stained with different fluorescent agents to visualize DNA (top), BrdU (middle), and anti-cyclin D antibody (bottom). Note that the two cells in this field injected with anti-cyclin D antibody (the red cells in the bottom micrograph) did not incorporate BrdU into nuclear DNA, as indicated by their lack of staining in the middle micrograph. (c) Percentage of control cells (blue bars) and experimental cells (red bars) that incorporated BrdU. Most cells injected with anti-cyclin D antibodies 10 or 12 hours after addition of growth factors failed to enter the S phase, indicated by the low level of BrdU incorporation. In contrast, anti-cyclin D antibodies had little effect on entry into the S phase and DNA synthesis when injected at 14 or 16 hours, that is, after cells had passed the restriction point. These results indicate that cyclin D is required to pass the restriction point, but once cells have passed the restriction point, they do not require cyclin D to enter the S phase 6–8 hours later. [Parts (b) and (c) adapted from V. Baldin et al., 1993, *Genes & Devel.* 7:812.]

differentiated cells, however, never reenter the cell cycle to replicate again. As we discuss in this section, the cell-cycle regulatory mechanisms uncovered in yeasts and *Xenopus* eggs and early embryos also operate in the somatic cells of higher eukaryotes, including humans and other mammals.

Mammalian Restriction Point Is Analogous to START in Yeast Cells

Most studies of mammalian cell-cycle control have been done with cultured cells that require certain polypeptide growth factors (mitogens) to stimulate cell proliferation.

Binding of these growth factors to specific receptor proteins that span the plasma membrane initiates a cascade of signal transduction that ultimately influences transcription and cell-cycle control (Chapters 15 and 16).

Mammalian cells cultured in the absence of growth factors are arrested with a diploid complement of chromosomes in the G_0 period of the cell cycle. If growth factors are added to the culture medium, these *quiescent cells* pass through the **restriction point** 14–16 hours later, enter the S phase 6–8 hours after that, and traverse the remainder of the cell cycle (see Figure 20-2). The restriction point is the time after addition of growth factors when cells no longer require the presence of growth factors to enter S phase. Like START in yeast cells, the restriction point is the point in the cell cycle at which mammalian cells become committed to entering the S phase and completing the cell cycle, which takes about 24 hours for most cultured mammalian cells.

Multiple CDKs and Cyclins Regulate Passage of Mammalian Cells Through the Cell Cycle

Unlike *S. pombe* and *S. cerevisiae*, which each produce a single cyclin-dependent kinase (CDK) to regulate the cell cycle, mammalian cells use a small family of related CDKs to regulate progression through the cell cycle. Four CDKs are expressed at significant levels in most mammalian cells and play a role in regulating the cell cycle. Named CDK1, 2, 4, and 6, these proteins were identified by the ability of their cDNA clones to complement certain *cdc* yeast mutants or by their homology to other CDKs.

Like *S. cerevisiae*, mammalian cells express multiple cyclins. Cyclin A and cyclin B, which function in the S phase, G_2 , and early mitosis, initially were detected as proteins whose concentration oscillates in experiments with synchronously cycling early sea urchin and clam embryos (see Figure 20-8). Homologous cyclin A and cyclin B proteins have been found in all multicellular animals examined. The cDNAs encoding three related human D-type cyclins and cyclin E were isolated based on their ability to complement *S. cerevisiae* cells mutant in all three genes encoding G_1 cyclins. The relative amounts of the three D-type cyclins expressed in various cell types differ. Here we refer to them collectively as cyclin D.

Cyclins D and E are the mammalian mid- and late- G_1 cyclins, respectively. Experiments in which cultured mammalian cells were microinjected with anti-cyclin D antibody at various times after addition of growth factors demonstrated that cyclin D is essential for passage through the restriction point (Figure 20-31).

Figure 20-32 presents a current model for the periods of the cell cycle in which different cyclin-CDK complexes act in G_0 -arrested mammalian cells stimulated to divide by the addition of growth factors. In the absence of growth factors, cultured G_0 cells express neither cyclins nor CDKs; the absence of these critical proteins explains why G_0 cells do not progress through the cell cycle and replicate.

Table 20-1, presented early in this chapter, summarizes the various cyclins and CDKs that we have mentioned and the portions of the cell cycle in which they are active. The cyclins fall

into two major groups, G_1 cyclins and B-type cyclins, which function in S, G_2 , and M. Although it is not possible to draw a simple one-to-one correspondence between the functions of the several cyclins and CDKs in *S. pombe*, *S. cerevisiae*, and vertebrates, the various cyclin-CDK complexes they form can be broadly considered in terms of their functions in mid- G_1 , late- G_1 , S, and M phases. All B-type cyclins contain a conserved destruction box sequence that is recognized by the APC/C-Cdh1 ubiquitin-protein ligase, whereas G_1 cyclins lack this sequence. Thus the APC/C regulates only the activity of those cyclin-CDK complexes that include B-type cyclins.

Regulated Expression of Two Classes of Genes Returns G_0 Mammalian Cells to the Cell Cycle

Addition of growth factors to G_0 -arrested mammalian cells induces transcription of multiple genes, most of which fall into one of two classes—*early-response* or *delayed-response* genes—depending on how soon their encoded mRNAs appear. Transcription of early-response genes is induced within a few minutes after addition of growth factors by signal-transduction cascades that activate preexisting transcription factors in the cytosol or nucleus (Chapter 16). Many of the early-response genes encode transcription factors, such as c-Fos and c-Jun, that stimulate transcription of the delayed-response genes. Mutant, unregulated forms of both c-Fos and c-Jun are expressed by oncogenic retroviruses (Chapter 25); the discovery that the activated viral forms of these proteins (v-Fos and v-Jun) can transform normal cells into cancer cells led to identification of the normal, regulated cellular forms of these transcription factors.

After peaking at about 30 minutes following addition of growth factors, the concentrations of the early-response mRNAs fall to a lower level that is maintained as long as growth factors are present in the medium. This decrease in early-response mRNA levels is mediated by early-response proteins.

Expression of delayed-response genes depends on proteins encoded by early-response genes. Some delayed-response genes encode additional transcription factors (see below); others encode mid- and late- G_1 cyclins and CDKs. The mid- G_1 cyclins and their associating CDKs are expressed first, followed by the late- G_1 cyclin and its CDK (see Figure 20-32). If growth factors are withdrawn before passage through the restriction point, transcription of the genes encoding these G_1 cyclins and CDKs ceases. Since these proteins and the mRNAs encoding them are unstable, their concentrations fall precipitously. As a consequence, the cells do not pass the restriction point and do not replicate.

In addition to being controlled by transcription of the gene encoding the mid- G_1 cyclin (cyclin D), the concentration of this cyclin is also regulated by controlling *translation* of cyclin D mRNA. In this regard, the mammalian mid- G_1 cyclin is similar to *S. cerevisiae* mid- G_1 cyclin. Addition of growth factors to cultured mammalian cells triggers signal transduction via the PI-3 kinase pathway discussed in Chapter 16, leading to activation of the mTOR pathway and the resulting activation of translation initiation factors (see

◀ **FIGURE 20-32 Activity of mammalian cyclin-CDK complexes through the course of the cell cycle.** Cultured G_0 cells are induced to divide by treatment with growth factors. The width of the colored bands is approximately proportional to the protein kinase activity of the indicated complexes. “Cyclin D” refers to all three D-type cyclins.

Figure 8-30). As a result, translation of cyclin D mRNA and other mRNAs is stimulated. Agents that inhibit activation of translation initiation factors, such as TGF- β , inhibit translation of cyclin D mRNA and thus inhibit cell proliferation.

Passage Through the Restriction Point Depends on Phosphorylation of the Tumor-Suppressor Rb Protein

Some members of a small family of related transcription factors, referred to collectively as *E2F factors*, are encoded by delayed-response genes. These transcription factors activate genes encoding many of the proteins involved in DNA synthesis. They also stimulate transcription of genes encoding the late- G_1 cyclin, the S-phase cyclin, and the S-phase CDK. Thus the E2Fs function in late G_1 similarly to the *S. cerevisiae* transcription factors SBF and MBF. In addition, E2Fs autostimulate transcription of their own genes. E2Fs function as transcriptional repressors when bound to *Rb protein*, which in turn binds histone deacetylase and methylase complexes. As discussed in Chapter 7, histone deacetylation and methylation of specific histone lysines causes chromatin to assume a condensed, transcriptionally inactive form.

Rb protein was initially identified as the product of the prototype **tumor-suppressor gene**, *RB*. The products of tumor-suppressor genes function in various ways to inhibit progression through the cell cycle (Chapter 25). Loss-of-function mutations in *RB* are associated with the disease *hereditary retinoblastoma*. A child with this disease inherits one normal RB^+ allele from one parent and one mutant RB^- allele from the other. If the RB^+ allele in any of the trillions of cells that make up the human body becomes mutated to a RB^- allele, then no functional Rb protein is expressed and the cell or one of its descendants is likely to become cancerous. For reasons that are not

understood, this generally happens in a retinal cell leading to the retinal tumors that characterize this disease. Subsequently it was discovered that Rb function is inactivated in almost all cancer cells, either by mutations in both alleles of *RB*, or by abnormal regulation of Rb phosphorylation. ■

Rb protein is one of the most significant substrates of mammalian G_1 cyclin-CDK complexes. Phosphorylation of Rb protein at multiple sites prevents its association with E2Fs, thereby permitting E2Fs to activate transcription of genes required for entry into S phase. As shown in Figure 20-33, phosphorylation of Rb protein is initiated by the mid- G_1 cyclin-CDK complexes in mid G_1 . Once the late- G_1 cyclin and CDK are induced by phosphorylation of some Rb, the resulting late- G_1 cyclin-CDK complex further phosphorylates Rb in late G_1 . When late- G_1 cyclin-CDK accumulates to a

▲ **FIGURE 20-33 Regulation of Rb and E2F activities in mid-late G_1 .** Stimulation of G_0 cells with mitogens induces expression of CDK4, CDK6, D-type cyclins, and the E2F transcription factors, all encoded by delayed-response genes. Rb protein initially inhibits E2F activity. When signaling from mitogens is sustained, the resulting cyclin D-CDK4/6 complexes begin phosphorylating Rb, releasing some E2F, which stimulates transcription of the genes encoding cyclin E, CDK2, and E2F itself (autostimulation). The cyclin E-CDK2 complexes further phosphorylate Rb, resulting in positive feedback loops (blue arrows) that lead to a rapid rise in the expression and activity of both E2F and cyclin E-CDK2 as the cell approaches the $G_1 \rightarrow S$ transition.

critical threshold level, further phosphorylation of Rb by the late-G₁ complex continues even when mid-G₁ cyclin-CDK activity is removed. This is one of the principal biochemical events responsible for passage through the restriction point. At this point, further phosphorylation of Rb by the late-G₁ cyclin-CDK occurs even when mitogens are withdrawn and mid-G₁ cyclin-CDK levels fall. Since E2F stimulates its own expression and that of the late-G₁ cyclin and CDK, positive cross-regulation of E2F and late-G₁ cyclin-CDK produces a rapid rise of both activities in late G₁.

As they accumulate, S-phase cyclin-CDK and mitotic cyclin-CDK complexes maintain Rb protein in the phosphorylated state throughout the S, G₂, and early M phases. After cells complete anaphase and enter early G₁ or G₀, the fall in cyclin-CDK levels leads to dephosphorylation of Rb. As a consequence, hypophosphorylated Rb is available to inhibit E2F activity during early G₁ of the next cycle and in G₀-arrested cells.

Cyclin A Is Required for DNA Synthesis and CDK1 for Entry into Mitosis

High levels of E2Fs activate transcription of the *cyclin A* gene as mammalian cells approach the G₁ → S transition. (Despite its name, cyclin A is a B-type cyclin, see Table 20-1.) Disruption of cyclin A function inhibits DNA synthesis in mammalian cells, suggesting that cyclin A is the S-phase cyclin and that, along with CDK2, it may function like *S. cerevisiae* S-phase cyclin-CDK complexes to trigger initiation of DNA synthesis. There is also evidence that the mammalian late-G₁ cyclin-CDK complexes also contribute to activation of prereplication complexes. Note that CDK2 complexes with both the late-G₁ and the S-phase cyclins (see Figure 20-32).

Three related CDK inhibitory proteins, or CKIs (p27^{KIP1}, p57^{KIP2}, and p21^{CIP}), appear to share the function of the *S. cerevisiae* S-phase inhibitor Sic1 (see Figure 20-28). Phosphorylation of p27^{KIP1} by late-G₁ cyclin-CDK targets it for polyubiquitination by the mammalian SCF complex (see Figure 20-28). The mechanisms for degrading p21^{CIP} and p57^{KIP2} are less well understood.

The activity of mammalian cyclin-CDK2 complexes is also regulated by phosphorylation and dephosphorylation mechanisms similar to those controlling the *S. pombe* mitosis-promoting factor, MPF (see Figure 20-14). The *Cdc25A phosphatase*, which removes the inhibitory phosphate from CDK2, is a mammalian equivalent of *S. pombe* Cdc25 except that it functions at the G₁ → S transition rather than the G₂ → M transition. The mammalian phosphatase normally is activated late in G₁, but is degraded in the response of mammalian cells to DNA damage to prevent the cells from entering S phase (see Section 20.7).

Once late-G₁ cyclin-CDK and S-phase cyclin-CDK are activated by Cdc25A and the S-phase inhibitors have been degraded, DNA replication is initiated at prereplication complexes. The general mechanism is thought to parallel that in *S. cerevisiae* (see Figure 20-30), although small differences are found in vertebrates. Phosphorylation of DNA

replication preinitiation complexes at replication origins by late-G₁ cyclin-CDK and S-phase cyclin-CDK likely promotes initiation of DNA replication. As in yeast, phosphorylation of these initiation factors likely prevents reassembly of pre-replication complexes until the cell passes through mitosis, thereby assuring that replication from each origin occurs only once during each cell cycle. In metazoans, a second small protein, geminin, contributes to the inhibition of reinitiation at origins until cells complete a full cell cycle. *Geminin* is expressed in late G₁; it binds and inhibits replication initiation factors as they are released from preinitiation complexes once DNA replication is initiated during S phase (Figure 20-30, step 3), contributing to the inhibition of re-initiation at an origin. Geminin contains a destruction box at its N-terminus that is recognized by the APC/C-Cdh1, causing it to be polyubiquitinated in late anaphase and degraded by proteasomes. This frees the replication initiation factors, which are dephosphorylated by Cdc14 phosphatase, to bind to ORC on replication origins forming preinitiation complexes during the following G₁ phase.

The principal mammalian CDK in G₂ and mitosis is CDK1 (see Figure 20-32). This CDK, which is highly homologous with *S. pombe* CDK, associates with cyclins A and B. The mRNAs encoding either of these mammalian cyclins can promote meiotic maturation when injected into *Xenopus* oocytes arrested in G₂ (see Figure 20-6), demonstrating that they function as mitotic cyclins. In somatic vertebrate cells, cyclin A-CDK1 and cyclin B-CDK1 function together as the equivalent of the *S. pombe* MPF (mitotic cyclin-CDK). The kinase activity of these mammalian complexes also is regulated by proteins analogous to those that control the activity of the *S. pombe* MPF (see Figure 20-14). The inhibitory phosphate on CDK1 is removed by *Cdc25C phosphatase*, which is analogous to *S. pombe* Cdc25 phosphatase.

In cycling mammalian cells, cyclin B is first synthesized late in the S phase and increases in concentration as cells proceed through G₂, peaking during metaphase and dropping after late anaphase. This parallels the time course of cyclin B expression in *Xenopus* cycling egg extracts (see Figure 20-9). In human cells, cyclin B first accumulates in the cytosol and then enters the nucleus just before the nuclear envelope retracts into the ER early in mitosis. Thus MPF activity is controlled not only by phosphorylation and dephosphorylation but also by regulation of its import into the nucleus. In fact, cyclin B shuttles between the nucleus and cytosol, and the change in its localization during the cell cycle results from a change in the relative rates of import and export. As in *Xenopus* eggs and *S. cerevisiae*, cyclins A and B are polyubiquitinated by the APC/C-Cdh1 complex during late anaphase and then are degraded by proteasomes (see Figure 20-10).

Two Types of Cyclin-CDK Inhibitors Contribute to Cell-Cycle Control in Mammals

As noted above, three related CKIs—p21^{CIP}, p27^{KIP1}, and p57^{KIP2}—inhibit late-G₁ cyclin-CDK and S-phase cyclin-CDK activity and must be degraded before DNA replication

can begin. These same CDK inhibitory proteins also can bind to and inhibit the other mammalian cyclin-CDK complexes involved in cell-cycle control. As we discuss later, p21^{CIP} plays a role in the response of mammalian cells to DNA damage. Experiments with knockout mice lacking p27^{KIP1} have shown that this CKI is particularly important in controlling generalized cell proliferation soon after birth. Although p27^{KIP1} knockouts are larger than normal, most develop normally otherwise. In contrast, p57^{KIP2} knockouts exhibit defects in cell differentiation, and most die shortly after birth owing to defective development of various organs.

A second class of cyclin-CDK inhibitors called *INK4s* (inhibitors of kinase 4) includes several small, closely related proteins that interact only with the mid-G₁ CDKs, CDK4 and CDK6, and thus function specifically in controlling the mid-G₁ phase. Binding of INK4s to CDK4 and CDK6 blocks their interaction with cyclin D and hence their protein kinase activity. The resulting decreased phosphorylation of Rb protein prevents transcriptional activation by E2Fs and entry into the S phase. One INK4 called *p16* is a tumor suppressor, like Rb protein discussed earlier. The presence of two mutant *p16* alleles in a large fraction of human cancers is evidence for the important role of *p16* in controlling the cell cycle (Chapter 25).

KEY CONCEPTS OF SECTION 20.6

Cell-Cycle Control in Mammalian Cells

- Various polypeptide growth factors called *mitogens* stimulate cultured mammalian cells to proliferate by inducing expression of early-response genes. Many of these encode transcription factors that stimulate expression of delayed-response genes encoding the G₁ CDKs, G₁ cyclins, and E2F transcription factors.
- Once cells pass the restriction point, they can enter the S phase and complete S, G₂, and mitosis in the absence of growth factors.
- Mammalian cells use several CDKs and cyclins to regulate passage through the cell cycle. Cyclin D–CDK4 and cyclin D–CDK6 function in mid to late G₁; cyclin E–CDK2, in late G₁ and early S; cyclin A–CDK2, in S; and cyclin A–CDK1 and cyclin B–CDK1 in G₂ and M through anaphase (see Figure 20-32).
- Unphosphorylated Rb protein binds to E2Fs, converting them into transcriptional repressors. Phosphorylation of Rb by the mid-G₁ cyclin-CDK liberates E2Fs to activate transcription of genes encoding the late-G₁ cyclin and CDK, as well as other proteins required for the S phase. E2Fs also autostimulate transcription of their own genes.
- The late-G₁ cyclin-CDK further phosphorylates Rb, further activating E2Fs. Once a critical level of late-G₁ cyclin-CDK has been expressed, a positive feedback loop with E2F results in a rapid rise of both activities that drives passage through the restriction point (see Figure 20-33).

- The activity of S-phase cyclin-CDK, induced by high E2F activity, initially is held in check by CKIs, which function like an S-phase inhibitor, and by the presence of an inhibitory phosphate on CDK2, the S-phase CDK. Proteasomal degradation of the inhibitors and activation of the Cdc25A phosphatase, as cells approach the G₁ → S transition, generate active S-phase cyclin-CDK. Along with the late-G₁ cyclin-CDK, this complex activates prereplication complexes to initiate DNA synthesis by a mechanism similar to that in *S. cerevisiae* (see Figure 20-30).

- Cyclin A–CDK1 and cyclin B–CDK1 induce the events of mitosis through early anaphase. Cyclins A and B are polyubiquitinated by the anaphase-promoting complex (APC/C) during late anaphase and then are degraded by proteasomes.

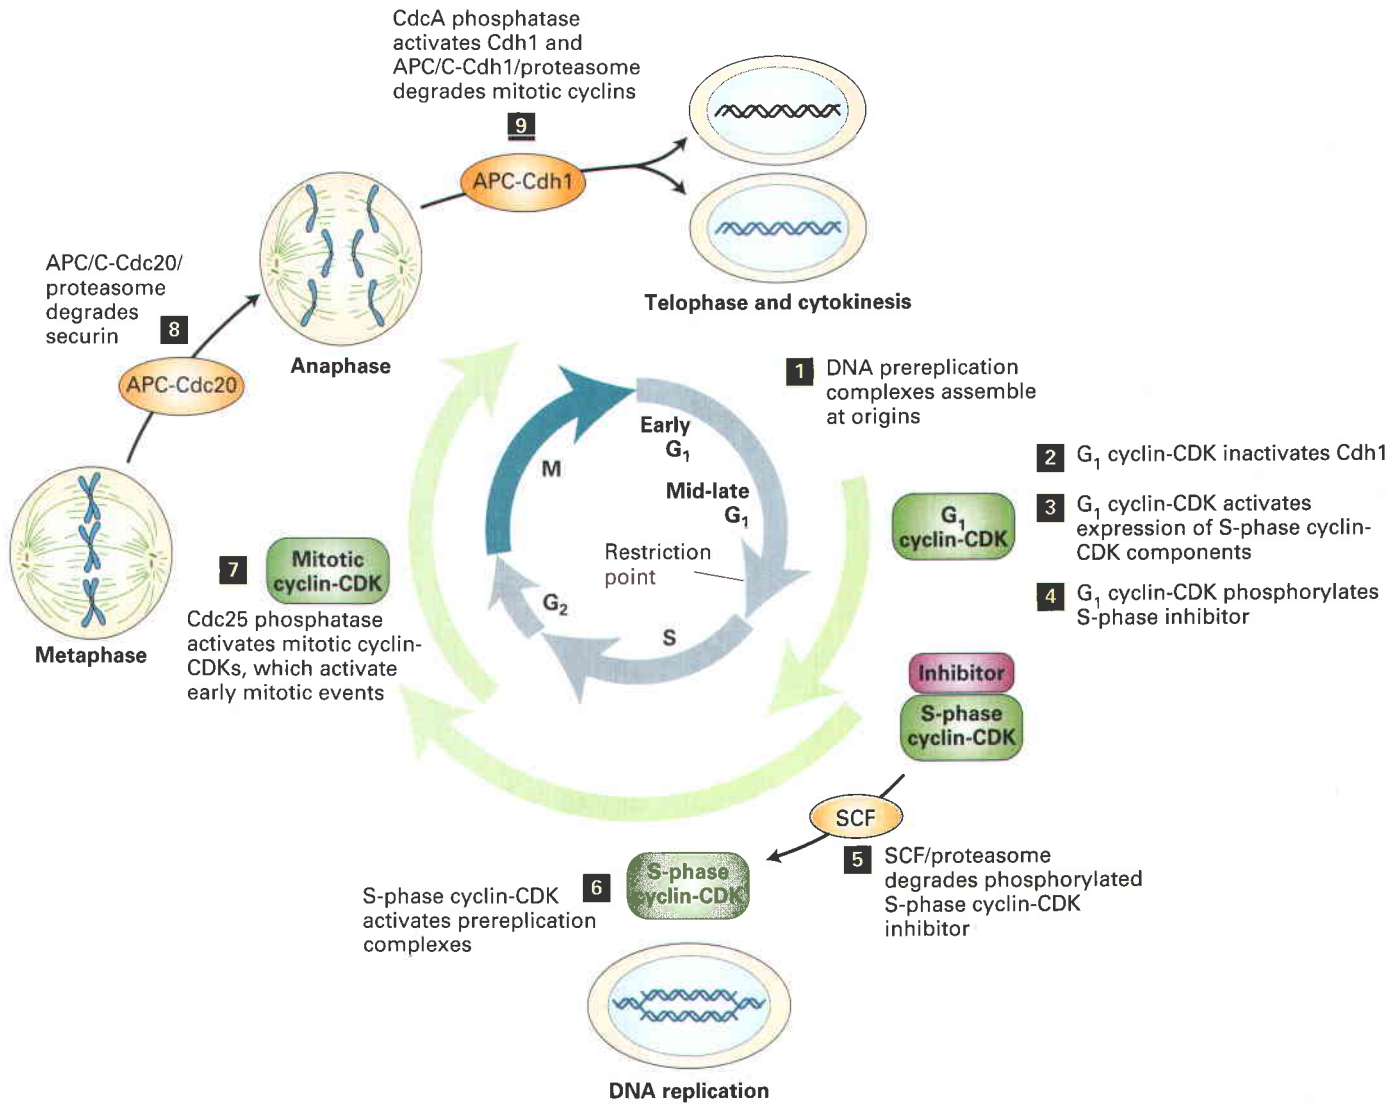

- The activity of mammalian mitotic cyclin-CDK complexes is regulated by phosphorylation and dephosphorylation similarly to the mechanism in *S. pombe*, with the Cdc25C phosphatase removing inhibitory phosphates (see Figure 20-14).

- The activities of mammalian cyclin-CDK complexes also are regulated by CDK inhibitors (CKIs), which bind to and inhibit each of the mammalian cyclin-CDK complexes, and INK4 proteins, which block passage through G₁ by specifically inhibiting G₁ CDKs (CDK4 and CDK6).

20.7 Checkpoints in Cell-Cycle Regulation

Before proceeding, let's review the major steps in the eukaryotic cell cycle summarized in Figure 20-34. In continuously cycling cells, cyclin-CDK complexes are absent in early G₁. Hypophosphorylated DNA replication initiation factors are free to bind to ORC complexes at DNA replication origins, generating prereplication complexes that are inactive until they are phosphorylated by an S-phase cyclin-CDK (step 1). In mid-G₁, mid-G₁ cyclin-CDKs are expressed and phosphorylate the APC/C specificity factor Cdh1, inactivating it and allowing newly synthesized B-type cyclins (and geminin in vertebrates) to accumulate when they are expressed (step 2). The mid-G₁ cyclin-CDKs also phosphorylate specific transcription factors, activating expression of late-G₁ and S-phase cyclins (and CDK in vertebrate somatic cells) (step 3). However, as B-type cyclins are expressed, they are immediately bound by inhibitors. When G₁ cyclin-CDK activities reach peak levels, they phosphorylate these inhibitors at multiple sites (step 4), marking them for polyubiquitination by the SCF ubiquitin-protein ligase, and subsequent degradation by proteasomes (step 5).

This rapid degradation of S-phase cyclin-CDK inhibitors releases S-phase cyclin-CDK activities, which phosphorylate key regulatory sites in prereplication complexes, stimulating initiation of DNA replication at multiple origins (step 6).

▲ **FIGURE 20-34** Fundamental processes in the eukaryotic cell cycle. See the text for discussion.

Mitotic cyclin-CDKs are expressed in late S phase and G₂. When DNA replication has been completed, they are activated by Cdc25 phosphatase, and either they, or other protein kinases that they activate, phosphorylate specific regulatory sites in more than a hundred proteins including histone H1, condensins and cohesins, additional chromatin-associated proteins, microtubule-associated proteins, nuclear lamins, inner nuclear membrane proteins, and nuclear pore complex proteins. These multiple, specific phosphorylations induce the early events of mitosis including chromosome condensation, remodeling of microtubules into the mitotic spindle apparatus, and, in animals and plants, retraction of the nuclear envelope into the ER (step 7).

Once every kinetochore of each sister chromatid has attached to spindle microtubule fibers during metaphase, inhibition of the Cdc20 specificity factor is lifted. This results in

active APC/C-Cdc20 and polyubiquitination and proteasomal degradation of securin (step 8). Securin degradation releases the proteolytic activity of separase, which then cleaves the cohesin rings at centromeres that hold sister chromatids together. The forces exerted by the mitotic spindle apparatus then pull the released sister chromatids toward opposite spindle poles. The resulting sudden separation of all sister chromatids marks the beginning of *anaphase*.

Once the daughter chromosomes have separated sufficiently to ensure equal segregation of all chromosomes to daughter cells during cytokinesis, the Cdc14 phosphatase is activated. Cdc14 dephosphorylates and activates the Cdh1 APC/C specificity factor, resulting in the polyubiquitination and proteasomal degradation of all B-type cyclins (and geminin in vertebrates), and consequently, the loss of MPF activity (step 9). Sites on the multiple proteins that were

phosphorylated by cyclin-CDKs are dephosphorylated by Cdc14. This returns the proteins to their interphase functions, resulting in decondensation of chromosomes, formation of an interphase microtubule cytoskeleton with a single microtubule organizing center, and reassembly of the nuclear envelope during telophase, followed by cytokinesis. The dephosphorylated DNA replication-initiation factors (released by geminin degradation in vertebrates) then reassemble preinitiation complexes on ORC complexes bound to replication origins in daughter cells, in preparation for the next cell cycle (step **1**).

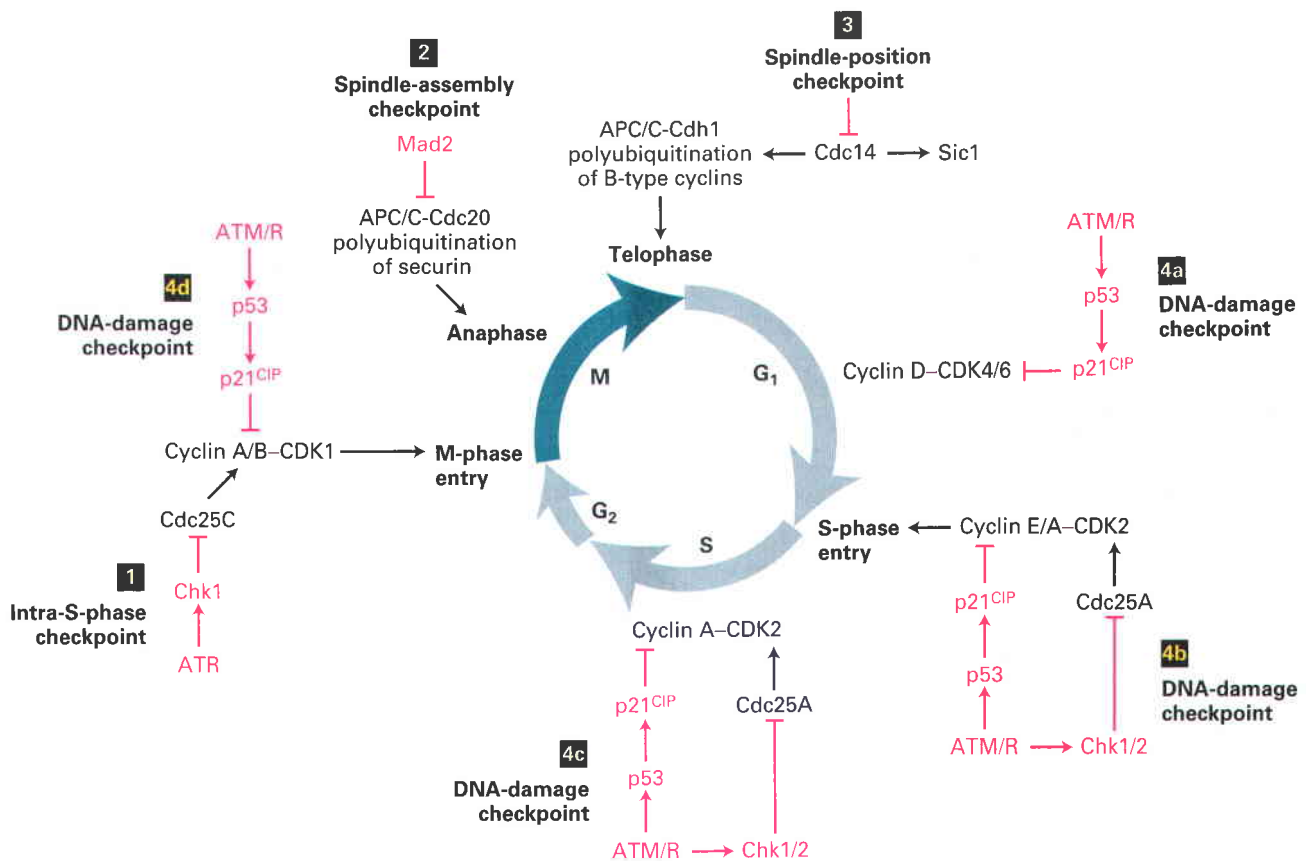

Successful completion of the cell cycle has several general requirements. Each process summarized in Figure 20-34 must go to completion before subsequent steps are undertaken, and the steps must occur in the correct order. Catastrophic genetic damage can occur if cells progress to the next phase of the cell cycle before the previous phase is properly completed. For example, when S-phase cells are induced to enter mitosis by fusion to a cell in mitosis, the MPF present in the mitotic cell forces the chromosomes of the S-phase cell to condense. This premature entry into mitosis results in fragmentation of the S-phase chromosomes, a disastrous consequence for a cell.

TABLE 20-2 Regulators of Cyclin-CDK Activity

TYPE OF REGULATOR	FUNCTION
KINASES AND PHOSPHATASES	
CAK kinase	Activates cyclin-CDKs
Wee1 kinase	Inhibits cyclin-CDKs
Cdc25 phosphatase	Activates cyclin-CDKs
Cdc14 phosphatase	Activates Cdh1 to inhibit mitotic cyclin-CDK
Cdc25A phosphatase	Activates vertebrate S-phase cyclin-CDK
Cdc25C phosphatase	Activates vertebrate mitotic cyclin-CDK
ATM/ATR kinases	Checkpoint controls, activate Chk1/Chk2 kinases
Chk1/Chk2 kinases	Checkpoint controls, inactivate Cdc25C and Cdc25A phosphatases to induce cell-cycle arrest
INHIBITORY PROTEINS	
Sic1	Binds and inhibits S-phase cyclin-CDKs
CKIs p27 ^{KIP1} , p57 ^{KIP2} , and p21 ^{CIP}	Bind and inhibit cyclin-CDKs
INK4	Binds and inhibits mid-G ₁ CDKs
Mad2	Spindle-assembly checkpoint control, binds Cdc20 and prevents onset of anaphase and inactivation of B-type cyclin-CDKs
Rb	Binds E2Fs, preventing transcription of multiple cell cycle genes
UBIQUITIN-PROTEIN LIGASES	
SCF	Degradation of phosphorylated Sic1 or p27 ^{KIP1} to activate S-phase cyclin-CDKs
APC/C + Cdc20	Induces degradation of Securin, initiating anaphase. Induces partial degradation of B-type cyclins
APC/C + Cdh1	Induces complete degradation of B-type cyclins to initiate telophase, and geminin in metazoans to allow formation of prereplication complexes on DNA replication origins

1 Another example of the importance of order of events in the cell cycle concerns attachment of kinetochores to microtubules of the mitotic spindle during metaphase. If anaphase is initiated before both kinetochores of a replicated chromosome become attached to microtubules from opposite spindle poles, daughter cells are produced that have missing or extra chromosomes, an outcome called *nondisjunction*. When nondisjunction occurs in mitotic cells, it can lead to the misregulation of genes, and contribute to the development of cancer. When nondisjunction occurs during the meiotic division that generates a human egg, Down syndrome can occur from trisomy of chromosome 21, resulting in developmental abnormalities and mental retardation. Other mechanisms can also generate trisomy. (Trisomy of any of the human chromosomes can occur, but for every other chromosome except chromosome 21, trisomy results in embryonic lethality or death shortly after birth.) **1**

We have seen how progression through the cell cycle is governed by precise regulation of the activities of multiple cyclin-CDK complexes. Table 20-2 summarizes the various types of regulators of cyclin-CDK activity. The key cell-cycle events of DNA replication and chromosome segregation must be accomplished with extraordinary accuracy and fidelity. To ensure that these processes occur correctly and in the proper order, cells have evolved multiple additional levels of regulation controlling these fundamental cell-cycle events. Collectively, these additional regulatory mechanisms are known as checkpoints (Figure 20-35). Several examples of cell-cycle checkpoints have been discussed earlier in the chapter. In this section, we consider these and additional checkpoints in terms of the major cell-cycle processes summarized above. Control mechanisms that operate at these checkpoints ensure that chromosomes are intact and that each stage of the cell cycle is completed before

▲ FIGURE 20-35 Overview of checkpoint controls in the cell cycle. The intra-S-phase checkpoint (**1**) prevents activation of cyclin A-CDK1 and cyclin B-CDK1 (i.e., mitosis-promoting factor, MPF) by activation of an ATR-Chk1 protein kinase cascade that phosphorylates and inactivates Cdc25C, thereby inhibiting entry into mitosis. In the spindle-assembly checkpoint (**2**), Mad2 and other proteins inhibit activation of the APC/C specificity factor Cdc20 required for polyubiquitination of securin, thereby preventing entry into anaphase. The spindle-position checkpoint (**3**) prevents release of the Cdc14 phosphatase from nucleoli, thereby blocking activation of the APC/C

specificity factor (Cdh1) required for APC/C polyubiquitination of B-type cyclins as well as induction of Sic1. As a result, the decrease in MPF activity required for the events of telophase does not occur. In the initial phase of the DNA-damage checkpoint (**4**), the ATM or ATR protein kinase (ATM/R) is activated. The active kinases then trigger two pathways: the Chk-Cdc25A pathway (**4b** and **4c**), blocking entry into or passage through S phase, and the p53-p21^{CIP} pathway, leading to arrest in G₁, S, and G₂ (**4a**–**4d**). See the text for further discussion. Red symbols indicate pathways that inhibit progression through the cell cycle.

TABLE 20-3 Checkpoint Proteins

CHECKPOINT	PURPOSE	SENSOR	ACTION
Intra-S phase checkpoint	Ensures all DNA replication is complete before entering M-phase	ATR detects replication forks	Inhibition of Cdc25C to prevent activation of mitotic cyclin-CDKs, blocking early mitotic events
Spindle-assembly checkpoint	Ensures all chromosome kinetochores are attached to spindle microtubules before anaphase	Mad2 detects kinetochores unattached to microtubules	Inhibition of Cdc20 to prevent activation of separase and onset of anaphase
Spindle-position checkpoint	Ensures all chromosomes are properly segregated to daughter cells before telophase and cytokinesis	(<i>S. cerevisiae</i>) Tem-1 detects proper position of spindle pole body in bud	Prevention of Cdc14 activation and degradation of mitotic cyclins, blocking late mitotic events
DNA-damage checkpoint	Detects damage to DNA throughout the cell cycle	ATM, ATR detect DNA damage	Inhibition of Cdc25A to prevent entry into S phase; p21 ^{CIP} inhibition of all cyclin-CDK complexes to induce cell cycle arrest

the following stage is initiated. Our understanding of these control mechanisms at the molecular level has advanced considerably in recent years. Table 20-3 lists four major cell cycle checkpoints and summarizes the control mechanisms used at each checkpoint.

The Presence of Unreplicated DNA Prevents Entry into Mitosis

Cells that fail to replicate all their chromosomes do not normally enter mitosis. Operation of the *intra-S-phase checkpoint* control involves the recognition of unreplicated DNA and stalled DNA replication forks, which causes inhibition of MPF activation (see Figure 20-35, **1**). Genetic studies in the yeasts and biochemical studies with *Xenopus* egg extracts demonstrated that the ATR and Chk1 protein kinases inhibit entry into mitosis by cells that have not completed DNA synthesis. The association of ATR with replication forks is thought to activate its protein kinase activity, leading to phosphorylation and activation of the Chk1 kinase. Active Chk1 then phosphorylates and inactivates the Cdc25 phosphatase (Cdc25C in vertebrates), which otherwise removes the inhibitory phosphate from mitotic CDKs. As a result, the mitotic cyclin-CDK complexes remain inhibited and cannot phosphorylate targets required to initiate mitosis. ATR continues to initiate this protein kinase cascade until all replication forks complete DNA replication and disassemble. This mechanism makes the initiation of mitosis *dependent* on the completion of chromosome replication. This dependency or requirement that a cell-cycle phase must be completed before the next phase can be initiated is a critical aspect of checkpoint function required

for orderly progression of the fundamental processes of the cell cycle (see Figure 20-34).

Improper Assembly of the Mitotic Spindle Prevents the Initiation of Anaphase

The *spindle-assembly checkpoint* prevents entry into anaphase until every single kinetochore of every chromatid is properly associated with spindle microtubules. If even a single kinetochore is unattached to a spindle microtubule, anaphase is inhibited. Clues about how this checkpoint operates initially came from isolation of yeast mutants in the presence of benomyl, a microtubule-depolymerizing drug. Low concentrations of benomyl increase the time required for yeast cells to assemble the mitotic spindle and attach kinetochores to microtubules. Wild-type cells exposed to benomyl do not begin anaphase until these processes are completed and then proceed on through mitosis, producing normal daughter cells. In contrast, mutants defective in the spindle-assembly checkpoint proceed through anaphase before assembly of the spindle and attachment of kinetochores is complete; consequently, they mis-segregate their chromosomes, producing abnormal daughter cells that die.

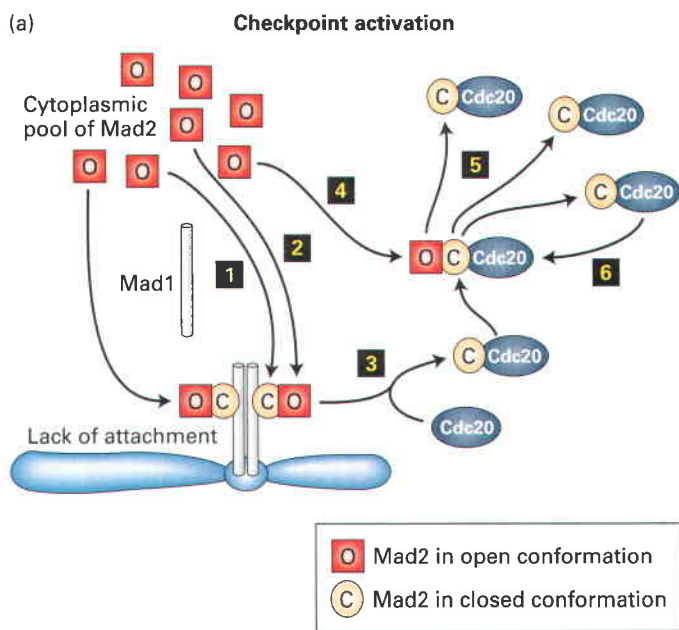

Analysis of these mutants identified a protein called *Mad2* (*mitotic arrest defective 2*) and other proteins that regulate Cdc20, the specificity factor required to target the APC/C to securin (see Figure 20-35, **2**). Recall that APC/C-Cdc20-mediated polyubiquitination of securin and its subsequent degradation is required for activation of separase and entry into anaphase (see Figure 20-23). Mad2 has been shown to associate with kinetochores that are unattached to microtubules. Kinetochore-bound Mad2 rapidly exchanges

with a soluble form of Mad2 that inhibits all the Cdc20 in the cell. When microtubules attach to kinetochores, the kinetochores release the bound Mad2 and cease the process by which the inhibitory, soluble form of Mad2 is produced. However, when even a single kinetochore is unattached to microtubules from the opposite spindle pole of its sister, sufficient soluble inhibitory Mad2 is produced at the unattached kinetochore to inhibit all the Cdc20 in the cell. The current model for how this regulatory mechanism functions (Figure 20-36) was suggested by X-ray crystallography and NMR data revealing the structures of interacting proteins involved in the process. The model is supported by directed mutagenesis studies guided by these structures, biochemical

studies of the protein-protein interactions, and microscopic studies in living cells using GFP-labeled proteins. This elegant model for the spindle-assembly checkpoint can account for the ability of a single unattached kinetochore to inhibit all the cellular Cdc20 until the kinetochore becomes properly associated with spindle microtubules.

Proper Segregation of Daughter Chromosomes Is Monitored by the Mitotic Exit Network

Once chromosomes have segregated properly, telophase commences. The various events of telophase and subsequent cytokinesis, collectively referred to as the *exit from*

▲ **FIGURE 20-36 Model for Cdc20 Regulation.** The spindle-assembly checkpoint is active until every single kinetochore has attached properly to spindle microtubules. (a) The Mad2 protein exists in two conformations, one “open” (red squares) and the other “closed” (orange circles). According to the current model, Mad2 in the open conformation can bind either Mad1 or Cdc20. Binding to Mad1 or Cdc20 converts Mad2 to the closed conformation, which is stably bound to these proteins. Cdc20 bound by the closed conformation of Mad2 is inactive. Two Mad2 proteins in the same conformation do not interact, but closed Mad2 and open Mad2 can bind to each other transiently through a site on Mad2 distinct from the one that associates with either Mad1 or Cdc20. Mad1 and the closed conformation of Mad2 form a tetramer that binds to unattached kinetochores via the Mad1 subunit (1). Mad2 in the open conformation can bind transiently to the Mad2 in the closed conformation bound to Mad1 at the kinetochore (2). This interaction with the closed Mad2 stimulates open Mad2 to bind a Cdc20. Open Mad2 can bind Cdc20 only while it is interacting with a closed Mad2. This converts the open Mad2 protein to the closed conformation, causing it to dissociate from the Mad2 in the closed conformation at the kinetochore (3). The stable interaction of closed Mad2 with Cdc20 prevents Cdc20 from binding to the APC/C. Further, the closed Mad2 bound to Cdc20 can interact transiently with another Mad2 in the open conformation (4), causing it to bind

another Cdc20 molecule. This converts this Mad2 to the closed conformation bound to Cdc20. This newly formed closed Mad2-Cdc20 complex dissociates from the first Mad2-Cdc20 pair, generating two Mad2-Cdc20 complexes (5). Thus free Mad2 in the open conformation is quickly converted to closed Mad2 bound to Cdc20 as this cycle repeats (6). The source of closed Mad2 that initiates this chain reaction is the closed Mad2 bound to Mad1 associated with a kinetochore, explaining how a single unattached kinetochore can cause inactivation of all the Cdc20 in the cell through the formation of closed Mad2-Cdc20 complexes. (b) Attachment of microtubules (green) to kinetochores causes the displacement of the Mad1/Mad2 tetramer. Mad2 in the displaced tetramer cannot interact with open Mad2, but rather, binds and activates another protein, p31^{comet}, which then binds Mad2 in Mad2-Cdc20 complexes, releasing active Cdc20 (7). However, a small number of Mad1-Mad2 tetramers bound to kinetochores can generate enough Mad2-Cdc20 complexes by the mechanism shown in (a) to overcome the activity of p31. Once all kinetochores have attached to microtubules causing the release of all Mad1-Mad2 tetramers, p31 activity predominates, releasing active Cdc20, which binds to the APC/C, resulting in polyubiquitination and proteasomal degradation of securin and the onset of anaphase. [Modified from A. De Antoni et al., 2005, *Curr. Biol.* 15:214; see also K. Nasmyth, 2005, *Cell* 120:739.]

mitosis, require inactivation of MPF. As discussed earlier, dephosphorylation of the APC/C specificity factor Cdh1 by the Cdc14 phosphatase leads to degradation of mitotic cyclins and loss of MPF activity late in anaphase (see Figure 20-10). During interphase and early mitosis, Cdc14 is sequestered in the nucleolus and inactivated. The *spindle-position checkpoint*, which monitors the location of the segregating daughter chromosomes at the end of anaphase, determines whether active Cdc14 is released from the nucleolus to promote exit from mitosis (see Figure 20-35, **B**).

Operation of this checkpoint in *S. cerevisiae* depends, in part, on a set of proteins referred to as the *mitotic exit network*. Regulation of Cdc14 activation operates similarly in most eukaryotes. In the fission yeast *S. pombe*, formation of the septum that divides daughter cells is regulated by proteins homologous to those that constitute the mitotic exit network in *S. cerevisiae*. Genes encoding similar proteins have been found in higher organisms where the homologs function in an analogous checkpoint that leads to arrest in late mitosis when daughter chromosomes do not segregate properly. A key component of the mitotic exit network is a small (monomeric) GTPase, called *Tem1* (Figure 20-37). This member of the GTPase superfamily of switch proteins controls the activity of a protein kinase cascade similarly to the way Ras controls MAP kinase pathways (Chapter 16). During anaphase, Tem1 becomes associated with the spindle pole body (SPB) closest to the daughter cell bud. (The SPB, from which spindle microtubules originate, is equivalent to the centrosome in higher eukaryotes.) At the SPB, Tem1 is maintained in the inactive GDP-bound state by a specific GAP (GTPase-activating protein). The GEF (guanine nucleotide-exchange factor) that activates Tem1 is localized to the cortex of the bud and is absent from the mother cell. Another protein, Kin4 protein kinase, is localized to the mother cell cortex and is absent from the bud. When spindle microtubule elongation at the end of anaphase has correctly positioned segregating daughter chromosomes into the bud, Tem1 comes into contact with its GEF and the Tem1-GAP becomes phosphorylated and inhibited. As a consequence, Tem1 is converted into its active GTP-bound state. The terminal kinase in the cascade triggered by Tem1-GTP then phosphorylates the nucleolar anchor that binds and inhibits Cdc14, releasing the Cdc14 phosphatase into the cytoplasm and nucleoplasm in both the bud and mother cell (Figure 20-37, **1**). Once active Cdc14 is available, a cell can proceed through telophase and cytokinesis.

The mitotic exit network is a good example of the dependency of one cycle phase on completion of the previous phase. Telophase and cytokinesis cannot initiate until the chromosome segregation mechanism carries daughter chromosomes into the bud. This is because initiation of telophase depends on the activation of Cdc14, and the activation of Cdc14 requires that Tem1 be pushed all the way to the bud cortex.

▲ FIGURE 20-37 The spindle-position checkpoint. Cdc14 phosphatase activity is required for the exit from mitosis. *Top:* In *S. cerevisiae*, during interphase and early mitosis, Cdc14 is sequestered and inactivated in the nucleolus. Inactive Tem1-GDP (purple) associates with the spindle pole body (SPB) nearest to the bud early in anaphase with the aid of a linker protein (blue) and is maintained in the inactive state by a specific GAP (GTPase-activating protein, yellow). If chromosome segregation occurs properly (**1**), extension of the spindle microtubules inserts the daughter SPB into the bud, causing Tem1 to come in contact with a specific GEF (guanine nucleotide-exchange factor) localized to the cortex of the bud (orange), and the inactivation of the Tem1-GAP. This converts inactive Tem1-GDP to active Tem1-GTP, which triggers a protein kinase cascade leading to release of active Cdc14 and exit from mitosis. If the spindle apparatus fails to place the daughter SPB in the bud (**2**), the SPB encounters Kin4 (cyan) localized to the mother cell cortex. This activates the Tem1-GAP, maintaining Tem1 in the inactive GDP-bound state and Cdc14 remains associated with nucleoli. Arrest in late mitosis results. [Adapted from G. Pereira and E. Schiebel, 2001, *Curr. Opin. Cell Biol.* **13**:762.]

If daughter chromosomes fail to segregate into the bud, Tem1 does not encounter the Tem1-GEF. Instead, the Kin4 kinase associated with the mother cell cortex maintains the Tem1-GAP in an activated state. Tem1, consequently, remains in its inactive, GDP-bound state, Cdc14 is not released from the nucleolus, and mitotic exit is blocked (Figure 20-37, **2**). Kin4 is not required in cells that segregate their chromosomes properly, but only in the small fraction of cells that fail to do so, giving them more time to push the daughter chromosomes into the bud. In *S. cerevisiae*, the

error rate for mis-segregation of chromosomes is <1 in 10^5 cell divisions.

Cell-Cycle Arrest of Cells with Damaged DNA Depends on Tumor Suppressors

 The proteins of the *DNA-damage checkpoint* sense DNA damage and block progression through the cell cycle until the damage is repaired. Damage to DNA can result from chemical agents and from irradiation with ultraviolet (UV) light or γ -rays. Arrest in G_1 and S prevents copying of damaged bases, which would fix mutations in the genome. Replication of damaged DNA also promotes chromosomal rearrangements that can contribute to the onset of cancer. Arrest in G_2 allows DNA double-stranded breaks to be repaired before mitosis. If a double-stranded break is not repaired, the broken distal portion of the damaged chromosome is not properly segregated because it is not physically linked to a centromere, which is pulled toward a spindle pole during anaphase.

As we discuss in detail in Chapter 25, inactivation of tumor-suppressor genes contributes to the development of cancer. The proteins encoded by several tumor-suppressor genes, including *ATM* and *Chk2*, normally function in the DNA-damage checkpoint. Patients with mutations in both copies of *ATM* or *Chk2* develop cancers far more frequently than normal. Both of these genes encode protein kinases.

DNA damage due to UV light is sensed by proteins that signal the presence of UV-damaged DNA to the ATM kinase, activating it. Activated ATM then phosphorylates and activates Chk2, which then phosphorylates the Cdc25A phosphatase, marking it for polyubiquitination by an ubiquitin-protein ligase and subsequent proteasomal degradation. Recall that removal of the inhibitory phosphate from mammalian CDK2 by Cdc25A is required for onset of and passage through the S phase, mediated by cyclin E-CDK2 and cyclin A-CDK2. Degradation of Cdc25A resulting from activation of the ATM-Chk2 pathway in G_1 or S-phase cells thus leads to G_1 or S arrest (see Figure 20-35, **4b** and **4c**). A similar pathway consisting of the protein kinases ATR and Chk1 leads to phosphorylation and polyubiquitination of Cdc25A in response to γ -irradiation. As discussed earlier for the intra-S-phase checkpoint, Chk1 also inactivates Cdc25C, preventing the activation of CDK1 and entry into mitosis.

Another tumor suppressor, **p53 protein**, contributes to arrest of cells with damaged DNA. Cells with functional p53 arrest in G_1 and G_2 when exposed to γ -irradiation, whereas cells lacking functional p53 do not arrest in G_1 . Although the p53 protein is a transcription factor, under normal conditions it is extremely unstable and generally does not accumulate to high enough levels to stimulate transcription. The instability of p53 results from its polyubiquitination by a ubiquitin-protein ligase called *Mdm2* and subse-

quent proteasomal degradation. The rapid degradation of p53 is inhibited by ATM and ATR, which phosphorylate p53 at a site that interferes with Mdm2 binding. This and other modifications of p53 in response to DNA damage greatly increase its ability to activate transcription of specific genes that help the cell cope with DNA damage. One of these genes encodes p21^{CIP}, a generalized CKI that binds and inhibits all mammalian cyclin-CDK complexes. As a result, cells are arrested in G_1 and G_2 until the DNA damage is repaired and p53, and subsequently p21^{CIP}, levels fall (see Figure 20-35, **4a–4d**).

Under some circumstances, such as when DNA damage is extensive, p53 also activates expression of genes that lead to apoptosis, the process of programmed cell death that normally occurs in specific cells during the development of multicellular animals. In vertebrates, the p53 response evolved to induce apoptosis in the face of extensive DNA damage, presumably to prevent the accumulation of multiple mutations that might convert a normal cell into a cancer cell. The dual role of p53 in both cell-cycle arrest and the induction of apoptosis may account for the observation that nearly all cancer cells have mutations in both alleles of the *p53* gene or in the pathways that stabilize p53 in response to DNA damage (Chapter 25). The consequences of mutations in *p53*, *ATM*, and *Chk2* provide dramatic examples of the significance of cell-cycle checkpoints to the health of a multicellular organism. ■

KEY CONCEPTS OF SECTION 20.7

Checkpoints in Cell-Cycle Regulation

- Checkpoint controls function to ensure that chromosomes are intact and that critical stages of the cell cycle are completed before the following stage is initiated.
- The intra-S-phase checkpoint operates during S and G_2 to prevent the activation of MPF before DNA synthesis is complete by inhibiting the activation of CDK1 by Cdc25C (see Figure 20-35, **1**).
- The spindle-assembly checkpoint, which prevents premature initiation of anaphase, utilizes Mad2 and other proteins to regulate the APC/C specificity factor Cdc20 that targets securin for polyubiquitination (see Figure 20-35, **2**, and Figure 20-36).
- The spindle-position checkpoint prevents telophase and cytokinesis until daughter chromosomes have been properly segregated, so that the daughter cell has a full set of chromosomes (see Figure 20-35, **3**).
- In the spindle-position checkpoint, the small GTPase Tem1 controls the availability of Cdc14 phosphatase, which in turn activates the APC/C specificity factor Cdh1 that targets B-type cyclins for degradation, causing inactivation of MPF (see Figure 20-10).
- The DNA-damage checkpoint arrests the cell cycle in response to DNA damage until the damage is repaired. Three

types of tumor-suppressor proteins (ATM/ATR, Chk1/2, and p53) are critical to this checkpoint.

- Activation of the ATM or ATR protein kinases in response to DNA damage due to UV light or γ -irradiation leads to arrest in G₁ and the S phase via a pathway that leads to loss of Cdc25A phosphatase activity. A second pathway from activated ATM/R stabilizes p53, which stimulates expression of p21^{CIP}. Subsequent inhibition of multiple CDK-cyclin complexes by p21^{CIP} causes prolonged arrest in G₁ and G₂ (see Figure 20-35, 4a–4d).
- In response to extensive DNA damage, p53 also activates genes that induce apoptosis.

20.8 Meiosis: A Special Type of Cell Division

In nearly all diploid eukaryotes, **meiosis** generates haploid germ cells (eggs and sperm), which can then fuse with a germ cell from another individual to generate a diploid zygote that develops into a new individual. Meiosis is a fundamental aspect of the biology and evolution of all eukaryotes because it results in the reassortment of the chromosome sets received from an individual's two parents. Both chromosome reassortment and **recombination** between parental DNA molecules during meiosis guarantees that each haploid germ cell generated will receive a unique combination of gene alleles that is distinct from each parent as well as from every other haploid germ cell formed.

The mechanisms of meiosis are analogous to those of mitosis. However, several key differences in meiosis allow this process to generate haploid cells with incredible genetic diversity (see Figure 5-3). In this section, we will discuss the parallels between molecular mechanisms of mitosis and meiosis, as well as the mechanistic differences responsible for the significant distinctions between these two fundamental processes of cell division.

Key Features Distinguish Meiosis from Mitosis

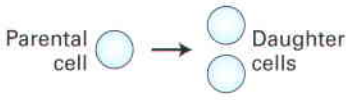

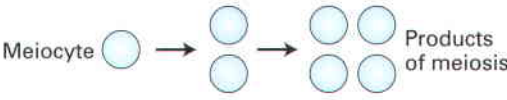

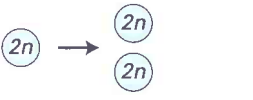

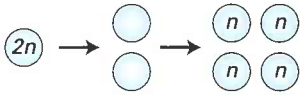

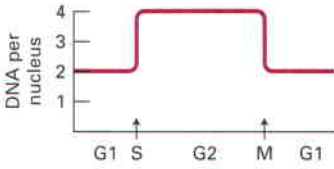

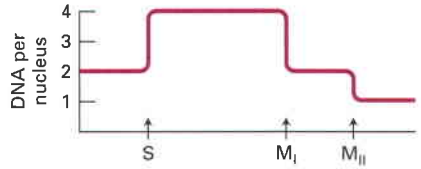

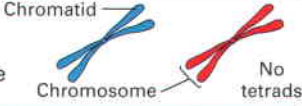

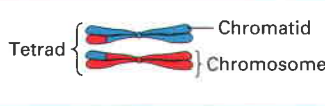

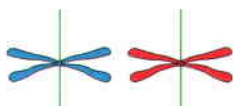

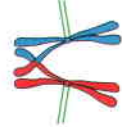

During meiosis (Figure 20-38), a single round of DNA replication is followed by two cycles of cell division, termed *meiosis I* and *meiosis II*, each distinct from the mitotic divisions of somatic cells. Figure 20-39 summarizes the distinctions between mitosis and meiosis. In G₂ and prophase of meiosis I, the two replicated chromatids of each chromosome (Figure 20-38, step 1) are associated with each other by cohesin complexes along the full length of the chromosome arms, just as they are following DNA replication in a mitotic cell cycle (see Figure 20-21, G₂ phase). A major difference between meiosis and mitosis is that in prophase of meiosis I, homologous chromosomes (i.e., the maternal and paternal chromosome 1, the maternal and paternal chromosome 2, etc.) pair with each other, a process known as *synapsis* (Figure 20-39, row 4). This forms a *bivalent chromo-*

► **FIGURE 20-38 Meiosis.** Premeiotic cells have two copies of each chromosome (2*n*), one derived from the paternal parent and one from the maternal parent. For simplicity, the paternal and maternal homologs of only one chromosome are diagrammed. Step 1: All chromosomes are replicated during the S phase before the first meiotic division, giving a 4*n* chromosomal complement. Cohesin complexes (not shown) link the sister chromatids composing each replicated chromosome along their full lengths. Step 2: As chromosomes condense during the first meiotic prophase, replicated homologs become paired as the result of at least one crossover event between a paternal and a maternal chromatid. This pairing of replicated homologous chromosomes is called *synapsis*. At metaphase, shown here, both chromatids of one chromosome associate with microtubules emanating from one spindle pole, but each member of a homologous chromosome pair associates with microtubules emanating from opposite poles. Step 3: During anaphase of meiosis I, the homologous chromosomes, each consisting of two chromatids, are pulled to opposite spindle poles. Step 4: Cytokinesis yields the two daughter cells (now 2*n*), which enter meiosis II without undergoing DNA replication. At metaphase of meiosis II, shown here, the chromatids composing each replicated chromosome associate with spindle microtubules from opposite spindle poles, as they do in mitosis. Steps 5 and 6: Segregation of chromatids to opposite spindle poles during the second meiotic anaphase followed by cytokinesis generates haploid germ cells (1*n*) containing one copy of each chromosome. Micrographs on the left show meiotic metaphase I and metaphase II in developing gametes from *Lilium* (Lily) ovules. Chromosomes are aligned at the metaphase plate. [Photos courtesy of Ed Reschke/Peter Arnold, Inc.]

some, or *tetrad*, composed of four homologous chromatids, two maternal and two paternal. Significantly, at least one recombination event occurs between a maternal and a paternal chromatid in every tetrad (Figure 20-39, row 5). The **crossing over** of chromatids produced by recombination can be observed microscopically in the first meiotic prophase and metaphase as structures called *chiasmata* (singular, *chiasma*). In contrast, no pairing between homologous chromosomes occurs during mitosis, and recombination between nonsister chromatids is rare.

Another key difference between mitosis and meiosis is that in the metaphase of meiosis I, the kinetochores at the centromeres of sister chromatids attach to spindle fibers emanating from the *same* spindle pole, rather than from opposite spindle poles as in mitosis. However, the kinetochores of the maternal and paternal chromosomes of each tetrad attach to spindle microtubules from opposite spindle poles (Figure 20-38, step 2; Figure 20-39, row 6). Also, cohesion between the full length of the sister chromatid arms is maintained throughout metaphase of meiosis I. This is in contrast to mitosis, where cohesion between sister chromatid arms is lost during prophase in mitotic cells from most organisms, so that cohesion is maintained only in the region of the centromere during mitotic metaphase (Figure 20-21; Figure 20-39, row 7). Because nonsister chromatids have recombined at least once by metaphase of meiosis I, and because cohesion is maintained between the arms of sister chromatids, as the maternal and paternal chromosomes are pulled toward opposite spindle poles in metaphase, the

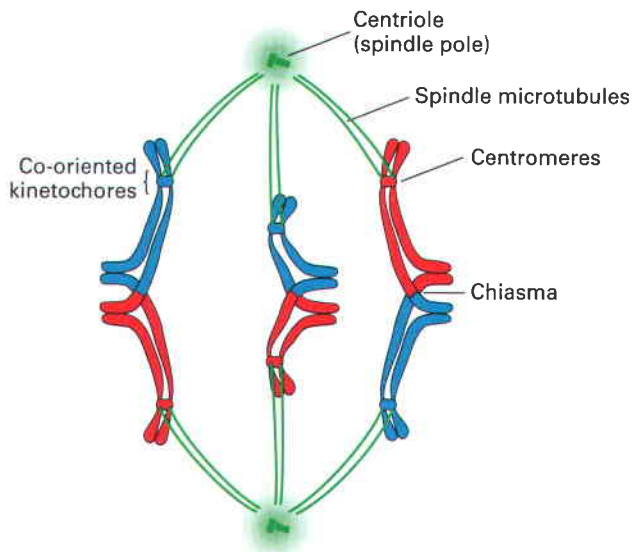

Row	Mitosis	Meiosis
	In somatic cells	In cells in the sexual cycle
1	One cell division, resulting in two daughter cells 	Two cell divisions, resulting in four products of meiosis 
2	Chromosome number per nucleus maintained (e.g., for a diploid cell) 	Chromosome number halved in the products of meiosis 
3	One premitotic S phase per cell division 	One premeiotic S phase for both cell divisions 
4	Normally, no pairing of homologous chromosomes in prophase 	Full synapsis of homologous chromosomes in prophase 
5	Normally, no recombination in prophase	At least one recombination between nonsister chromatids 
6	Bi-oriented sister kinetochores 	Co-orientation of sister kinetochores 
7	Loss of cohesion between sister chromatid arms during metaphase	Maintenance of cohesion between sister chromatid arms during metaphase of meiosis I
8	Centromeres divide at anaphase 	Centromeres do not divide at anaphase I but do at anaphase II 
9	Conservative process: daughter cells' genotypes identical with parental genotype	Promotes variation among the products of meiosis
10	Cell undergoing mitosis can be diploid or haploid	Cell undergoing meiosis is diploid

▲ **FIGURE 20-39 Comparison of the main features of mitosis and meiosis.** [Adapted from A. J. F. Griffiths et al., 1999, *Modern Genetic Analysis*, W.H. Freeman and Company.]

homologous chromosomes are held together by the chiasmata between them and cohesion of the sister chromatids distal to the crossover (Figure 20-40). During anaphase of meiosis I, securin degradation releases separase, which then cleaves the cohesin rings holding the chromosome arms together as during mitosis (Figure 20-23). However, during meiosis I, cohesin rings at the centromere are not cleaved (Figure 20-39, row 8). This allows the recombinant maternal and paternal chromosomes to separate, but each pair of chromatids remains associated at the centromere (Figure 20-38, step 5; Figure 20-39, row 8).

In some organisms, meiosis II proceeds without decondensation of the chromosomes and assembly of a nuclear envelope. In other organisms, these typical interphase events

occur, but the interphase is short and nuclear envelope retraction into the ER and chromosome condensation of meiotic prophase II follow rapidly. During metaphase II (Figure 20-38, step 4), as in mitosis, the kinetochores of each sister chromatid attach to spindle microtubules from opposite spindle poles. Also, as during mitosis, cohesion between the chromatid arms is lost and maintained only in the region of the centromere. When the final kinetochore is properly attached to a spindle microtubule, anaphase II occurs (Figure 20-38, step 5), followed by telophase II and cytokinesis to generate four haploid germ cells (Figure 20-38, step 6). For each chromosome, at least two of the haploid germ cells have recombinant chromosomes generated from recombination between maternal and paternal chromosomes during

▲ **FIGURE 20-40 Cohesion between homologous chromosomes in meiosis I metaphase.** Connections between chromosomes during meiosis I are most easily visualized in organisms with acrocentric centromeres, such as the grasshopper. The kinetochores at the centromeres of sister chromatids attach to spindle microtubules emanating from the same spindle pole, with the kinetochores of the maternal (red) and paternal (blue) chromosomes attaching to spindle microtubules from opposite spindle poles. The maternal and paternal chromosomes are attached at the chiasmata formed by recombination between them and the cohesion between sister chromatid arms that persists throughout meiosis I metaphase. Note that elimination of cohesion between sister chromatid arms is all that is required for the homologous chromosomes to separate at anaphase. [Adapted from L. V. Paliulis and R. B. Nicklas, 2000, *J. Cell Biol.* 150:1223.]

prophase of meiosis I (Figure 20-38, step 2). Thus the recombination between nonsister chromatids that occurs in prophase of meiosis I has at least two functional consequences: First, it holds homologous chromosomes together during meiosis I metaphase (Figure 20-40). Second, it contributes to genetic diversity among individuals of a species by ensuring new combinations of gene alleles in different individuals. Genetic diversity also arises from the independent reassortment of maternal and paternal homologs during the meiotic divisions.

Repression of G_1 Cyclins and a Meiosis-Specific Protein Kinase Promote Premeiotic S Phase

In *S. cerevisiae* and *S. pombe*, depletion of nitrogen and carbon sources induces diploid cells to undergo meiosis, yielding haploid spores (see Figure 1-6). This process is analogous to the formation of germ cells in higher eukaryotes. Multiple yeast mutants that cannot form spores have been isolated, and the wild-type proteins encoded by these genes have been analyzed. These studies have identified specialized cell-cycle proteins required for meiosis.

Under starvation conditions, expression of G_1 cyclins in *S. cerevisiae* is repressed, blocking the normal progression of G_1 in cells as they complete mitosis. Instead, a set of early meiotic proteins is induced. Among these is *Ime2*, a protein kinase closely homologous to CDKs that performs the essential G_1 cyclin-CDK functions required to enter S phase: (1) phosphorylation of the APC/C specificity factor Cdh1, inactivating it so that B-type cyclins can accumulate, (2) phosphorylation of transcription factors to induce genes required for S phase including DNA polymerases and S-phase cyclins and CDKs, and (3) phosphorylation of the S-phase inhibitor Sic1, leading to release of active S-phase cyclin-CDK complexes and the onset of DNA replication in meiosis I.

The cell uses *Ime2* during meiosis rather than the standard G_1 cyclin-CDKs so that its protein kinase activity can be regulated differently. While the transcription and translation of G_1 cyclins required for activity of G_1 cyclin-CDKs is repressed in nutrient-starved cells, the transcription and translation of *Ime2* is activated. Also, the *Ime2* kinase activity is regulated differently than for the G_1 cyclins. It does not require a cyclin partner for kinase activity and is not regulated by the same protein kinases and phosphatases that regulate the activities of G_1 cyclin-CDKs.

The mechanism by which DNA replication is suppressed between meiosis I and II is currently an active area of investigation. Following meiosis I anaphase, MPF activity does not fall as low as it does following mitotic anaphase. This intermediate level of MPF activity is required for normal meiosis II. It appears that MPF activity falls low enough to allow partial or complete cytokinesis, but not low enough to allow dephosphorylation of DNA replication initiation factors. Presumably, DNA replication does not occur between meiosis I and II in part because DNA replication initiation factors are maintained in a hyperphosphorylated form that cannot assemble prereplication complexes on DNA (see Figure 20-30). A second rise in MPF activity occurs that is required for formation of the meiosis II spindle. After all sister kinetochores have attached to microtubules from opposite spindle poles, the activity of Cdc20 is derepressed, separase is activated and cells proceed into meiosis II anaphase (Figure 20-38, step 5), telophase, and cytokinesis, to generate haploid germ cells.

Recombination and a Meiosis-Specific Cohesin Subunit Are Necessary for the Specialized Chromosome Segregation in Meiosis I

As discussed earlier, in metaphase of meiosis I, both sister chromatids in one (replicated) chromosome associate with microtubules emanating from the *same* spindle pole, rather than from opposite poles as they do in mitosis. Two physical links between homologous chromosomes are thought to resist the pulling force of the spindle until anaphase: (a) crossing over between chromatids, one from each pair of homologous chromosomes, and (b) cohesin cross-links between sister chromatids distal to the crossover point (see Figure 20-40).

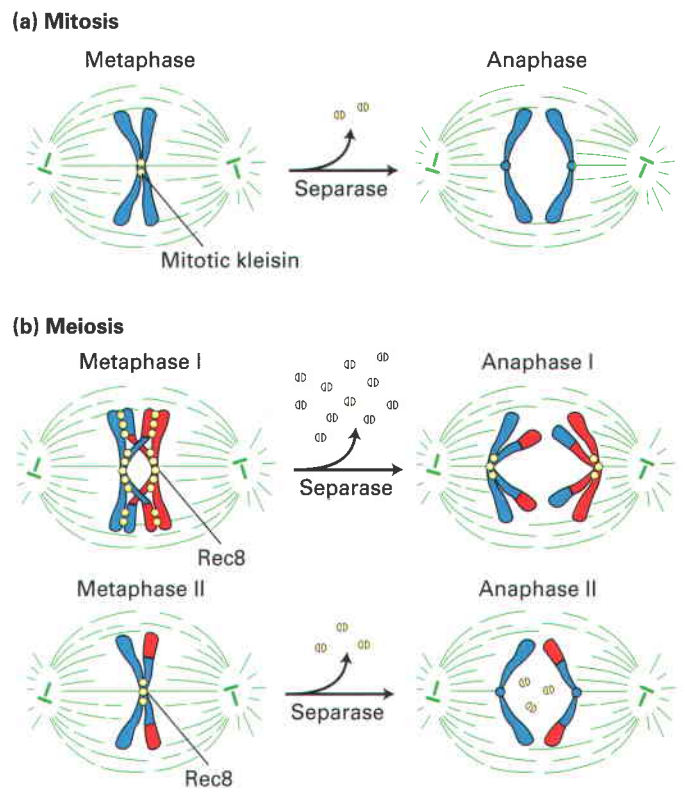

Evidence for the function of recombination during meiosis in *S. cerevisiae* comes from the observation that when recombination is blocked by mutations in proteins essential for the process, chromosomes segregate randomly during meiosis I; that is, homologous chromosomes do not necessarily segregate to opposite spindle poles. Such segregation to opposite spindle poles normally occurs because both chromatids of the maternal and paternal homologous chromosome pairs associate with spindle fibers emanating from opposite spindle poles (see Figure 20-38, step 3, and Figure 20-40). As discussed above, this in turn requires that homologous chromosomes pair during prophase of meiosis I. Consequently, the finding that mutations that block recombination also block proper segregation in meiosis I implies that recombination is required for synapsis of homologous chromosomes in *S. cerevisiae*.

Unlike the mitotic anaphase (Figure 20-41a), at the onset of meiotic anaphase I, the cohesin cross-links between chromosome arms are cleaved by separase, allowing the homologous chromosomes to separate, but cohesin complexes at the centromere remain linked (Figure 20-41b, top). The maintenance of centromeric cohesion during meiosis I is necessary for the proper segregation of chromatids during meiosis II. Studies with a *S. pombe* mutant have shown that a specialized cohesin kleisin subunit (see Figure 20-23), *Rec8*, maintains centromeric cohesion between sister chromatids during meiosis I. Expressed only during meiosis, *Rec8* is homologous to the cohesin subunit that closes the cohesin ring in the cohesin complex of mitotic cells. Immunolocalization experiments in *S. pombe* revealed that during early anaphase of meiosis I, *Rec8* is lost from chromosome arms but is retained at centromeres. However, during early anaphase of meiosis II, centromeric *Rec8* is degraded by separase, so the chromatids can segregate, as they do in mitosis (Figure 20-41b, bottom). *S. cerevisiae* *Rec8* has been shown to localize and function similarly to *S. pombe* *Rec8*, and homologs of *Rec8* also have been identified in higher organisms. Consequently, understanding the regulation of *Rec8*-cohesin complex cleavage is central to understanding chromosome segregation in meiosis I.

Micromanipulation experiments during grasshopper spermatogenesis indicated that chromosome-associated factors protect centromeric *Rec8* from cleavage during meiosis I but not during meiosis II. These experiments also demonstrated that the attachment of sister kinetochores to microtubules emanating from the same spindle pole during meiosis I, as opposed to attachment to spindle fibers from opposite spindle poles in meiosis II and mitosis, also results from factors associated with the chromosomes (Figure 20-42). Thus crossing over, *Rec8*, and special kinetochore-associated proteins appear to function in meiosis in all eukaryotes.

Special Properties of *Rec8* Regulate Its Cleavage in Meiosis I and II

The mechanism that protects *S. cerevisiae* *Rec8* from degradation at centromeres during meiosis I is similar to the mech-

▲ **FIGURE 20-41 Cohesin function during mitosis and meiosis.**

(a) During mitosis, sister chromatids generated by DNA replication in the S phase are initially associated by cohesin complexes along the full length of the chromatids. During chromosome condensation, cohesin complexes (yellow) become restricted to the region of the centromere at metaphase, as depicted here. Once separase cleaves the kleisin cohesin subunit (see Figure 20-23), sister chromatids can separate, marking the onset of anaphase. (b) In prophase of meiosis I, recombination between maternal and paternal chromatids produces synapsis of homologous parental chromosomes. By metaphase the chromatids of each replicated chromosome are cross-linked by cohesin complexes along their full length. *Rec8*, a meiosis-specific homolog of the mitotic kleisin, is cleaved in chromosome arms but not in the centromere, allowing homologous chromosome pairs to segregate to daughter cells. Centromeric *Rec8* is cleaved during meiosis II, allowing individual chromatids to segregate to daughter cells. [Modified from F. Uhlmann, 2001, *Curr. Opin. Cell Biol.* 13:754.]

anism that protects kleisin cohesin subunits at centromeres during mitosis. Recall that during mitotic prophase, protein kinases activated by the mitotic cyclin-CDKs phosphorylate cohesins in the chromatid arms, causing them to dissociate, eliminating cohesion in chromatid arms by metaphase in most organisms. However, cohesion at the centromeres is maintained because a specific isoform of protein phosphatase 2A (PP2A) is localized to centromeric chromatin and keeps cohesin in a hypophosphorylated state that does not dissociate from chromatin (see Figure 20-22). Then, when the last kinetochore is properly associated with spindle microtubules, *Cdc20* is derepressed and associates with the APC/C, causing polyubiquitination of securin. This releases separase activity, which cleaves the kleisin whether it is

▲ EXPERIMENTAL FIGURE 20-42 Anaphase movements and cohesion of meiotic chromosomes are determined by proteins associated with the chromosomes. Grasshopper spermatocytes in meiosis I and II were fused so that both types of spindles with their associated chromosomes were present in a single fused cell. Then a micromanipulation needle was used to move some meiosis I chromosomes and meiosis II chromosomes from one spindle to another; other chromosomes were left attached to their normal spindles. After 70 minutes, both spindles with their attached chromosomes had completed anaphase movements. The paired meiosis I chromosomes separated normally (i.e., one homologous

pair toward one spindle pole and the other homologous pair toward the other) whether attached to the meiosis I spindle (*left*) or meiosis II spindle (*right*). Similarly, the meiosis II chromosomes separated normally (i.e., one chromatid toward one spindle pole and the other chromatid toward the opposite pole) independent of which spindle they were attached to. These results indicate that the association of kinetochores with spindle microtubules and the stability of cohesins linking chromosomes are determined by factors that are associated with the chromosomes and not by the spindles or soluble components of cells in meiosis I and II. [See L. V. Paliulis and R. B. Nicklas, 2000, *J. Cell Biol.* **150**:1223.]

phosphorylated or not, eliminating cohesion at the centromere and allowing chromatid separation in anaphase (see Figure 20-41a).

This mechanism differs for meiosis I because when Rec8 replaces the mitotic kleisin in the cohesin complex, the complex does not dissociate in prophase when it is phosphorylated by mitotic protein kinases. Rec8 also differs from the mitotic kleisin in that it must be phosphorylated by these mitotic protein kinases to be cleaved by separase. During meiosis I the centromere-specific isoform of PP2A is bound to centromeric chromatin by a linker protein called *shugoshin* (Japanese for “guardian spirit”). However, shugoshin is not expressed during meiosis II.

These properties of Rec8 and shugoshin are required for the specialized chromosome segregation of meiosis I. Cohesin linkages between daughter chromatids are maintained in the

chromosome arms because Rec8-containing cohesin complexes are resistant to dissociation when they are phosphorylated by the mitotic protein kinases. They are cleaved, however, when Cdc20 is a derepressed and separase is activated because the required phosphorylation by these mitotic protein kinases has occurred. This results in loss of cohesion at sister chromatid arms, which is all that is necessary for homologous chromosomes to dissociate at meiosis I anaphase (Figure 20-40 and Figure 20-41b, *top*). However, cohesion between sister chromatid centromeres is maintained because shugoshin is expressed in meiosis I and binds PP2A to the centromere, where it dephosphorylates nearby Rec8, making it resistant to cleavage by separase. In meiosis II, there is no cohesion between chromatid arms because cohesin complexes were removed from the arms during meiosis I anaphase. Since shugoshin is not expressed in meiosis II, PP2A is not localized to

centromeric chromatin and centromeric cohesin is not protected from phosphorylation by the mitotic protein kinases that are activated by the second rise in mitotic cyclin-CDK activity during meiosis II prophase. Consequently, when separase is activated at the end of meiosis II metaphase, Rec8 in centromeric cohesin is cleaved, allowing the sister chromatids to be pulled to opposite spindle poles.

The Monopolin Complex Co-orient Sister Kinetochores in Meiosis I

As discussed earlier, in mitosis and meiosis II, sister kinetochores attach to spindle microtubules emanating from *opposite* spindle poles; the kinetochores are said to be *bi-oriented*. This is essential for segregation of sister chromatids to different daughter cells. In contrast, at meiosis I metaphase, sister kinetochores attach to spindle microtubules emanating from the *same* spindle pole; the sister kinetochores are said to be *co-oriented*. Obviously, attachment of sister kinetochores to the proper microtubules in meiosis I and II is critical for correct meiotic segregation of chromosomes.

Identification of a protein required for sister kinetochore cohesion in *S. cerevisiae* began with DNA microarray analysis of *S. cerevisiae* that revealed genes expressed in meiosis and not mitosis. Systematic knockout of each of these genes revealed that when one, *MAM1* (*monopolar microtubule attachment during meiosis I*) encoding a protein called *monopolin*, was inactivated, sister chromatids in metaphase of meiosis I associated with spindle microtubules emanating from opposite spindle poles, as though they were mitotic chromatids or chromatids in meiosis II.

Identification of proteins that interact with monopolin and in vivo fluorescence microscopy studies with GFP-labeled proteins revealed two proteins that form a *monopolin complex* with monopolin that are also found at kinetochores in mitotic cells and cells in meiosis II. These results have led to the model that the monopolin complex clamps microtubule binding sites in the sister kinetochores in the same orientation so that they interact with the + end of microtubules coming from the same spindle pole. In the absence of monopolin in meiosis II and mitotic cells, the other subunits of the monopolin complex that are expressed are proposed to clamp the spindle microtubule binding sites of sister chromatids in the opposite orientation so they can bind only the + ends of microtubules coming from opposite directions.

Tension on Spindle Microtubules Contributes to Proper Spindle Attachment

Additional micromanipulation experiments and genetic experiments in yeast have provided considerable evidence that stable attachment of spindle microtubules to kinetochores, and the stability of the microtubules themselves, requires that the microtubules be under tension during metaphase. If microtubules from the wrong spindle pole attach to sister chromatids early in metaphase, motor

proteins and microtubule shortening do not produce tension on the microtubules because both kinetochores are pulled in the same direction. However, when attachment occurs to the microtubules from the correct poles, tension is developed because the kinetochores are pulled in opposite directions. During meiotic metaphase I, kinetochore-associated microtubules are also under tension (even though the co-oriented kinetochores of sister chromatids attach to microtubules coming from the same spindle pole) because chiasmata generated by recombination between homologous chromosomes prevent them from being pulled to the poles (see Figure 20-40). Since kinetochore binding to microtubules is unstable in the absence of tension, kinetochores that attach to the wrong spindle fibers release the incorrect microtubules, enabling them to bind microtubules again until attachments are made that generate tension. Once tension is generated, microtubule attachment to the kinetochores is stabilized.

KEY CONCEPTS OF SECTION 20.8

Meiosis: A Special Type of Cell Division

- Meiosis involves one cycle of chromosome replication followed by two cycles of cell division to produce haploid germ cells from a diploid premeiotic cell (see Figure 20-38).
- During meiosis I, replicated homologous chromosomes pair along their lengths in a process called synapsis. At least one recombination event between chromatids of homologous chromosomes almost invariably occurs.
- Most of the cell-cycle proteins that function in mitotically dividing cells also function in cells undergoing meiosis, but some proteins are unique to meiosis.
- In *S. cerevisiae*, expression of G₁ cyclins is repressed throughout meiosis. Meiosis-specific Ime2 performs the function of G₁ cyclin-CDK complexes in promoting initiation of DNA replication during meiosis I.
- In *S. cerevisiae*, recombination (crossing over) between chromatids of homologous parental chromatids as well as cohesin cross-links between chromatids distal to the crossover are responsible for holding the homologous chromosomes together during prophase and metaphase of meiosis I. A specialized cohesin subunit, Rec8, replaces the mitotic kleisin cohesin subunit during meiosis.
- At the onset of early anaphase of meiosis I, Rec8 in the chromosome arms is cleaved, but a meiosis-specific protein associated with the kinetochore protects Rec8 from cleavage in the region of the centromere. As a result, the chromatids of homologous chromosomes remain associated during segregation in meiosis I. Cleavage of centromeric Rec8 during anaphase of meiosis II allows individual chromatids to segregate into germ cells (see Figure 20-41b).
- Monopolin, another meiosis-specific protein complex, is required for both chromatids of homologous chromosomes to associate with microtubules emanating from the same spindle poles during meiosis I.

Perspectives for the Future

The remarkable pace of cell-cycle research over the last 25 years has led to the model of eukaryotic cell-cycle control outlined in Figure 20-34. A beautiful logic underlies these molecular controls. Each regulatory event has two important functions: to activate a step of the cell cycle and to prepare the cell for the next event of the cycle. This strategy ensures that the phases of the cycle occur in the proper order.

Although the general logic of cell-cycle regulation now seems well established, many critical details remain to be discovered. For instance, although researchers have identified some components of the prereplication complex that must be phosphorylated by S-phase cyclin-CDK complexes to initiate DNA replication, other components remain to be determined. As discussed earlier, substantial progress has been made recently in identifying substrates phosphorylated by mitotic cyclin-CDK complexes. Much work remains to be done to understand how the modification of these proteins leads to chromosome condensation and the remarkable reorganization of microtubules that results in assembly of the beautiful mitotic spindle. Much remains to be learned about how the activities of Wee1 kinase and Cdc25 phosphatase are controlled; these proteins in turn regulate the kinase activity of the CDK subunit in most cyclin-CDK complexes.

Much has been discovered recently about the operation of cell-cycle checkpoints, but the mechanisms that activate ATM and ATR in the DNA-damage checkpoint are poorly understood. Likewise, much remains to be learned about the control and mechanism of regulation of Mad2 in the spindle-assembly checkpoint, and of Cdc14 in the chromosome-segregation checkpoint in higher cells. As we learn in the next chapter, asymmetric cell division plays a critical role in the normal development of multicellular organisms. Many questions remain about how the plane of cytokinesis and the localization of daughter chromosomes are determined in cells that divide asymmetrically. Similarly, the mechanisms that underlie the unique segregation of chromatids during meiosis I have not been elucidated yet.

 Understanding these detailed aspects of cell-cycle control will have significant consequences, particularly for the treatment of cancers. Cancer cells often have defects in cell-cycle checkpoints that led to the accumulation of multiple mutations and DNA rearrangements that result in the cancer phenotype. However, the absence of these checkpoints can make specific types of cancers particularly vulnerable to extensive DNA damage induced with radiation therapy or chemotherapy. Normal cells activate cell-cycle checkpoints that arrest the cell cycle until the DNA damage is repaired. But these cancer cells do not, and as a consequence suffer sufficient genetic damage to induce apoptosis. If more were understood about cell-cycle controls and checkpoints, it might be possible to design ever more effective therapeutic strategies, especially against types of cancer that are largely resistant to today's conventional therapies. It seems very likely that better understanding

of the molecular processes involved will allow the design of more effective treatments in the future. ■

Key Terms

anaphase-promoting complex (APC/C) 850	mitogens 880
APC/C specificity factor 858	mitosis-promoting factor (MPF) 855

Review the Concepts

1. What strategy ensures that passage through the cell cycle is unidirectional and irreversible? What is the molecular machinery that underlies this strategy?
2. When fused with an S-phase cell, cells in which of the following phases of the cell cycle will initiate DNA replication prematurely—G₁? G₂? M? Predict the effect of fusing a cell in G₁ and a cell in G₂ with respect to the timing of S phase in each cell.
3. Tim Hunt shared the 2001 Nobel prize for his work in the discovery and characterization of cyclin proteins in eggs and embryos. What experimental evidence indicates that cyclin B is required for a cell to enter mitosis? What evidence indicates that cyclin B must be destroyed for a cell to exit mitosis?
4. In *Xenopus*, one of the substrates of MPF is the Cdc25 phosphatase. When phosphorylated by MPF, Cdc25 is activated. What is the substrate of Cdc25? How does this information help to explain the rapid rise in MPF activity as cells enter mitosis?
5. In 2001, the Nobel prize in physiology or medicine was awarded to three cell-cycle scientists. Sir Paul Nurse was recognized for his studies with the fission yeast *S. pombe*, in particular for the discovery and characterization of the *wee1* gene. What is the *wee* phenotype? What did the characterization of the *wee1* gene tell us about cell-cycle control?
6. Three known substrates of MPF or kinases regulated by MPF are the nuclear lamins, nucleoporins, and subunits of

condensin. Describe how the phosphorylation of each of these proteins affects its function and progression through mitosis.

7. Describe the series of events by which the APC/C promotes the separation of sister chromatids at anaphase.
8. At the end of telophase, nuclear envelope extensions from the ER fuse around each chromosome to form karyomeres that then fuse to form daughter-cell nuclei. What are the roles of Ran-GEF and Ran-GTP in this process?
9. Explain how CDK activity is modulated by the following proteins: (a) cyclin, (b) CAK, (c) Wee1, (d) p21.
10. A common feature of cell-cycle regulation is that the events of one phase ensure progression into a subsequent phase. In *S. cerevisiae*, mid- and late-G₁ cyclin-CDKs catalyze progression through G₁, and multiple B-type cyclin-CDK complexes catalyze progression through S, G₂, and M. Name three ways in which the activities of mid- and late-G₁ cyclin-CDKs promote the activation of S-phase and mitotic cyclin-CDK complexes.
11. For S phase to be completed in a timely manner, DNA replication initiates from multiple origins in eukaryotes. In *S. cerevisiae*, what role do S-phase cyclin-CDK complexes play to ensure that the entire genome is replicated once and only once per cell cycle?
12. What is the functional definition of the restriction point? Cancer cells typically lose restriction-point controls. Explain how the following mutations, which are found in some cancer cells, lead to a bypass of restriction-point controls: (a) overexpression of cyclin D, (b) loss of Rb function, (c) infection by retroviruses encoding v-Fos and v-Jun.
13. The Rb protein has been called the “master brake of the cell cycle.” Describe how the Rb protein acts as a cell-cycle brake. How is the brake released in mid to late G₁ to allow the cell to proceed to the S phase?
14. Leeland Hartwell, the third recipient of the 2001 Nobel prize, was acknowledged for his characterization of cell-cycle checkpoints in the budding yeast *S. cerevisiae*. What is a cell-cycle checkpoint? Where do checkpoints occur in the cell cycle? How do cell-cycle checkpoints help to preserve the fidelity of the genome?
15. What role does p53 play in mediating cell-cycle arrest for cells with DNA damage?
16. Individuals with the hereditary disorder ataxia telangiectasia suffer from neurodegeneration, immunodeficiency, and increased incidence of cancer. The genetic basis for ataxia telangiectasia is a loss-of-function mutation in the ATM gene (ATM = *ataxia telangiectasia-mutated*). Besides p53, what other substrate is phosphorylated by ATM? How does the phosphorylation of this substrate lead to inactivation of CDKs to enforce cell-cycle arrest at a checkpoint?
17. Meiosis and mitosis are overall analogous processes involving many of the same proteins. However, some proteins function uniquely in each of these cell-division events. Explain the meiosis-specific function of the following: (a) Ime2, (b) Rec8, (c) monopolin.

Analyze the Data

Many of the proteins that regulate transit through the cell cycle have been characterized. Recently, a new protein, Xnf7, has been identified in extracts of *Xenopus* eggs. This protein binds to the anaphase-promoting complex/cyclosome (APC/C). To elucidate the function of this protein, studies have been undertaken in which Xnf7 either has been depleted from extracts using an antibody raised against it, or has been augmented in the extracts through addition of extra Xnf7. The consequences on transit through mitosis were then assessed (see J. B. Casaletto et al., 2005, *J. Cell Biol.* 169: 61–71).

a. *Xenopus* egg extracts, arrested in metaphase, were either depleted of Xnf7 or were mock-depleted (subjected to the same treatment as the first sample but without Xnf7 antibody), then released from metaphase arrest by addition of Ca²⁺. Aliquots of the extract were then sampled at various times after Ca²⁺ addition and the amounts of cyclin B determined, as shown on the Western blot below. What information do these data provide about a possible function for Xnf7?

b. In additional studies, exogenous Xnf7 was added to *Xenopus* egg extracts, arrested at metaphase, so that the total amount of this protein in the extracts was higher than normal. The extracts, released from arrest by Ca²⁺ addition, were then assessed at various times after release for cyclin B ubiquitination (cyclin-Ub conjugates). What is the rationale for examining ubiquitination? Using the following figure, determine what information these studies add beyond that obtained from part (a)?

c. The spindle checkpoint prevents cells with unattached kinetochores from proceeding into anaphase. Thus, cells in which this checkpoint has been activated do not enter anaphase and do not degrade cyclin B. Nocodazole, a drug that prevents microtubule assembly, can be used to

activate the spindle checkpoint. Cells in nocodazole become arrested in early mitosis because they cannot form a spindle, and thus all kinetochores remain unattached. To determine if Xnf7 is required for a functional spindle checkpoint, *Xenopus* egg extracts, arrested in metaphase, were subjected to various protocols (see the following figure): untreated (–nocodazole), or treated with nocodazole and either mock-depleted (preimmune) or immuno-depleted of Xnf7 (α -Xnf7). The extracts were then treated with Ca^{2+} to overcome arrest, and aliquots of the extracts were assessed at various times for cyclin B, as shown on the Western blot below. What can you conclude about Xnf7 from these data?

CELL BIOLOGY EMERGING FROM THE SEA: THE DISCOVERY OF CYCLINS

T. Evans et al., 1983, *Cell* 33:391.

From the first cell divisions after fertilization to aberrant divisions that occur in cancers, biologists have long been interested in how cells control when they divide. The processes of cell division have been separated into stages known collectively as the *cell cycle*. While studying early development in marine invertebrates in the early 1980s, Joan Ruderman and Tim Hunt discovered the cyclins, key regulators of the cell cycle.

Background

The question of how an organism develops from a fertilized egg continues to drive a large body of scientific research. Whereas such research was classically the concern of embryologists, the developing understanding of gene expression in the 1980s brought new approaches to answer this question. One such approach was to examine the pattern of gene expression in both the oocyte and the newly fertilized egg. Ruderman and Hunt were among the biologists who took this approach to the study of early development.

Biologists had well characterized the early development of a number of marine invertebrate systems. During the early stages of development, the embryonic cells grow synchronously, which allows an entire population of cells to be studied at the same stage of the cell cycle. Researchers had established that a large portion of the mRNA in the unfertilized oocyte is not translated. Upon fertilization, these maternal mRNA are rapidly translated. Previous studies had shown that when fertilized eggs are treated with drugs that inhibit protein synthesis, cell division could not take place. This suggested that the initial burst of pro-

tein synthesis from the maternal mRNA is required at the earliest stages of development. Ruderman and Hunt, while teaching a physiology course at the Marine Biological Lab in Woods Hole, Massachusetts, began a set of experiments designed to uncover the genes that were expressed at this point as well as the mechanism by which this burst of protein synthesis was controlled.

The Experiment

In a collaborative project, Ruderman and Hunt looked at regulation of gene expression in the fertilized egg of the surf clam *Spisula solidissima*. Whereas it was known that overall protein synthesis rapidly increased upon fertilization, they wanted to find out whether the proteins expressed in the earliest stage of development, the two-cell embryo, were different from those expressed in the unfertilized egg. When either oocytes or two-cell clam embryos are treated with radioactively labeled amino acids, the cell takes up the amino acids, which are subsequently incorporated into newly synthesized proteins. Using this technique, Ruderman and Hunt monitored the pattern of protein synthesis by breaking open the cells, separating the proteins using SDS-polyacrylamide gel electrophoresis (SDS-PAGE), and then visualizing the radioactively labeled proteins by autoradiography. When they compared the pattern of protein synthesis in the oocyte with that in the two-cell embryo, they saw that three different proteins that were either not expressed or expressed at an extremely low level in the oocyte were highly expressed in the embryo. In a subsequent study, Ruderman examined the pattern of protein expression in the oocytes of the

starfish *Asterias forbesi* as they mature. She again observed the increased expression of three proteins of similar size to those that she and Hunt had seen in surf clam embryos.

Soon afterward, in a third study, Hunt examined the changes in protein expression during the maturation and fertilization of sea urchin oocytes. This time he performed the experiment in a slightly different manner. Rather than treating the oocytes and embryo with radioactively labeled amino acids for a set time period, he labeled the cells continuously for more than 2 hours, removing samples for analysis at 10-minute intervals. Now, he could monitor the changes in protein expression throughout the early stages of development. As had been shown in other organisms, the pattern of protein synthesis was altered when the sea urchin oocyte was fertilized. Three proteins—represented by three prominent bands on an autoradiograph—were expressed in the embryos, but not in the oocytes. Interestingly, the intensity of one of these bands changed over time; the band was intense at the early time points, then barely visible after 85 minutes. It increased in intensity again between 95 and 105 minutes. The intensity of the band, representing the amount of the protein in the cell, appeared to be oscillating over time. This suggested that the protein had been quickly degraded and then synthesized again.

Because the time frame of the experiment coincided with early embryonic cell divisions, Hunt next asked whether the synthesis and destruction of the protein was correlated with progression of the cell cycle. He examined a portion of cells from each time point under a microscope, counting the number of cells dividing at each time

◀ **FIGURE 1** This figure compares the changing levels of sea urchin cyclin (drawn in blue) with a control protein (drawn in purple) as early embryonic cells progress through the cell cycle. The overall level of cyclin increases over time, and then it is rapidly destroyed as the cells approach division. This pattern appears to repeat through each cell division. Meanwhile, the overall level of the control protein continues to increase throughout the time period of the experiment. [Adapted from T. Evans et al., 1983, *Cell* **33**:391.]

point where samples had been taken for protein analysis. Hunt then correlated the amount of the protein present in the cell with the proportion of cells dividing at each time point. He noticed that the level of expression of one of the proteins was highest before the cell divided and lowest upon cell division (see Figure 1), suggesting a correlation with the stage of the cell cycle. When the same experiment was performed in the surf clam, Hunt saw that two of the proteins that he and Ruderman had described previously displayed the same pattern of synthesis and destruction. Hunt called these proteins *cyclins* to reflect their changing expression through the cell cycle.

Discussion

The discovery of the cyclins heralded an explosion of investigation into the cell cycle. It is now known that these proteins regulate the cell cycle by associating with cyclin-dependent kinases, which in turn regulate the activities of a variety of transcription and replication factors, as well as other proteins involved in the complex alterations in cell architecture and chromosome structure that occur during mitosis. In brief, cyclin-CDK complexes direct and regulate through the cell cycle. As with so many key regulators of cellular functions, it was soon shown that the cyclins discovered in sea urchins and surf clams are conserved in eukaryotes

from yeast to man. Since the identification of the first cyclins, scientists have identified at least 15 other cyclins that regulate all phases of the cell cycle.

In addition to the basic research interest in these proteins, the cyclins' central role in cell division has made them a focal point in cancer research. Cyclins are involved in the regulation of several genes that are known to play prominent roles in tumor development. Scientists have shown that at least one cyclin, cyclin D1, is overexpressed in a number of tumors. The role of these proteins in both normal and aberrant cell division continues to be an active and exciting area of research today.

CELL BIRTH, LINEAGE, AND DEATH

During the evolution of multicellular organisms, new mechanisms arose to diversify cell types, to coordinate their production, to regulate their size and number, to organize them into functioning tissues, and to eliminate extraneous or aged cells. Signaling between cells became even more important than it was for single-celled organisms. The mode of reproduction also changed, with some cells becoming specialized as **germ cells** (e.g., eggs, sperm), which give rise to new organisms, as distinct from all other body cells, called **somatic cells**. Under normal conditions somatic cells will never be part of a new individual.

The formation of working tissues and organs during **development** of multicellular organisms depends in part on specific patterns of mitotic cell division. A series of such cell divisions akin to a family tree is called a *cell lineage*. A cell lineage traces the birth order of cells, the progressive restriction of their developmental potential, and their **differentiation** into specialized cell types (Figure 21-1). Cell lineages are controlled by cell-intrinsic (internal) factors—cells acting according to their history and internal regulators—as well as by cell-extrinsic (external) factors such as cell–cell signals and environmental inputs. A cell lineage begins with **stem cells**, unspecialized cells that can potentially reproduce themselves and generate more-specialized cells indefinitely. Their name comes from the image of a plant stem, which grows upward, continuing to form more stem, while sending off leaves and branches to the side. A cell lineage ultimately culminates in formation of terminally differentiated cells such as skin cells, neurons, or

muscle cells. Terminal differentiation generally is irreversible, and the resulting highly specialized cells often cannot divide; they survive, carry out their functions for varying lengths of time, and then die.

Many cell lineages contain intermediate cells, referred to as *precursor cells* or *progenitor cells* or, if they are rapidly dividing, *transient amplifying (TA) cells*. The potential of such intermediate cells to form different kinds of differentiated cells is more limited than that of the stem cells from which they arise. (Although some researchers distinguish between precursor and progenitor cells, we will use these terms interchangeably.) Once a new precursor cell type is created, it often produces **transcription factors** characteristic of its fate. These transcription factors coordinately activate, or repress,

21.1 The Birth of Cells: Stem Cells, Niches, and Lineage

▲ FIGURE 21-1 Overview of the birth, lineage, and death of cells. Following growth, cells are “born” as the result of symmetric or asymmetric cell division. (a) The two daughter cells resulting from symmetric division are essentially identical to each other and to the parental cell. Such daughter cells subsequently can have different fates if they are exposed to different signals. The two daughter cells resulting from asymmetric division differ from birth and consequently have different fates. Asymmetric division commonly is preceded by the localization of regulatory molecules (green dots) in one part of the parent cell. (b) A series of symmetric and/or asymmetric cell divisions, called a cell lineage, gives birth to each of the specialized cell types found in a multicellular organism. The pattern of cell lineage can be under tight genetic control. Programmed cell death occurs during normal development (e.g., in the webbing that initially develops when fingers grow) and also in response to infection or poison. A series of specific programmed events, called apoptosis, is activated in these situations.

batteries of genes that direct the differentiation process. For instance, a few key regulatory transcription factors create the different mating types of budding yeast and similarly, a small number of such factors produced in sequence trigger the steps in forming differentiated muscle cells from precursors. We discuss both these examples in this chapter.

Typically we think of cell fates in terms of the differentiated cell types that are formed. A quite different cell fate, **programmed cell death**, also is absolutely crucial in the formation and maintenance of many tissues. A precise genetic regulatory system, with checks and balances, controls cell death just as other genetic programs control cell differentiation. In this chapter, then, we consider the life cycle of cells—their birth, their patterns of division (lineage), and their death. These aspects of cell biology converge with developmental biology and are among the most important processes regulated by the signaling pathways discussed in earlier chapters.

Many descriptions of cell division imply that the parental cell gives rise to two daughter cells that look and behave exactly like the parental cell: that is, cell division is *symmetric*, and the progeny retain the same properties as the parental cell. But if this were always the case, none of the hundreds of differentiated cell types present in complex organisms would ever be formed. Differences among cells can arise when two initially identical daughter cells diverge upon receiving distinct developmental or environmental signals. Alternatively, the two daughter cells may differ from “birth,” with each inheriting different parts of the parental cell (see Figure 21-1). Daughter cells produced by such **asymmetric cell division** may differ in size, shape, and/or composition, or their genes may be in different states of activity or potential activity. The differences in these internal signals confer different fates on the two cells.

Here we discuss some general features of how different cell types are generated, culminating with the best-understood complex cell lineage, that of the nematode *Caenorhabditis elegans*. In later sections, we focus on examples of the molecular mechanisms that determine particular cell types in yeast, *Drosophila*, and mammals.

Stem Cells Give Rise to Both Stem Cells and Differentiating Cells

Stem cells, which give rise to the specialized cells composing the tissues of the body, exhibit several patterns of cell division (Figure 21-2). A stem cell may divide symmetrically

▲ FIGURE 21-2 Patterns of stem-cell division. Divisions of stem cells (yellow) must maintain the stem-cell population, sometimes increase the number of stem cells, and at the right time produce differentiating cells (green). (a) Stem cells that undergo asymmetric divisions produce one stem cell and one differentiating cell. This does not increase the population of stem cells. (b) Some stem cells in a population may divide symmetrically to increase their population, which may be useful in normal development or during recovery from injury, while at the same time others are dividing asymmetrically as in (a). (c) In a third pattern, some stem cells may divide as in (b), while at the same time others produce two differentiating progeny. [Adapted from S. Morrison and J. Kimble, 2006, *Nature* 441:1068.]

to yield two daughter stem cells identical to itself. Alternatively, a stem cell may divide asymmetrically to generate a copy of itself and a derivative stem cell that has more-restricted capabilities, such as dividing for a limited period of time or giving rise to fewer types of progeny compared with the parental stem cell. A *pluripotent* (or multipotent) stem cell has the capability of generating a number of different cell types, but not all. For instance, a pluripotent blood stem cell will form more of itself plus multiple types of blood cells, but never a skin cell. In contrast, a *unipotent* stem cell divides to form a copy of itself plus a cell that can form only one cell type. For example stem cells in the intestine continuously reproduce themselves, while the other daughter cell differentiates into an intestinal epithelial cell, as we discuss in greater detail below. In many cases, asymmetric division of a stem cell generates a progenitor cell, which embarks on a path of differentiation, or even a terminally differentiating cell.

The two critical properties of stem cells that together distinguish them from all other cells are the ability to reproduce themselves indefinitely, often called *self-renewal*, and the ability to divide asymmetrically to form one daughter stem cell identical to itself and one daughter cell of more restricted potential. Many stem-cell divisions are symmetric, producing two stem cells, but at some point some progeny need to differentiate. In this way, mitotic division of stem cells can either enlarge a population of undifferentiated cells or maintain a stem-cell population while steadily producing a stream of differentiating cells. Although some types of precursor cells can divide symmetrically to form more of themselves, they do so only for limited periods of time. Moreover, in contrast to stem cells, if a precursor cell divides asymmetrically, it generates two distinct daughter cells, neither of which is identical to the parental precursor cell.

The fertilized egg, or *zygote*, is the ultimate *totipotent* cell because it has the capability to generate all the cell types of the body. Although not technically a stem cell because it is not self-renewing, the zygote does give rise to cells with stem-cell properties. For example, the early mouse embryo passes through an eight-cell stage in which each cell can form every tissue; that is, they are totipotent. Thus the subdivision of body parts and tissue fates among the early embryonic cells has not irreversibly occurred at the eight-cell stage. At the 16-cell stage, this is no longer true; some of the cells are committed to particular differentiation paths.

Cell Fates Are Progressively Restricted During Development

The eight cells resulting from the first three divisions of a mammalian zygote (fertilized egg) all look the same. As demonstrated experimentally in sheep, each of the cells has the potential to give rise to a complete animal. Additional divisions produce a mass, composed of ≈ 64 cells, that sepa-

ECTODERM	MESODERM	ENDODERM
Central nervous system	Skull	Stomach
Retina and lens	Head, skeletal muscle	Colon
Cranial and sensory ganglia and nerves	Skeleton	Liver
Pigment cells	Dermis of skin	Pancreas

Epidermis	Urogenital system	Epithelial parts of trachea
Hair	Heart	lungs
Mammary glands	Blood, lymph cells	pharynx
	Spleen	thyroid
		intestine

▲ **FIGURE 21-3 Fates of the germ layers in animals.** Some of the tissue derivatives of the three germ layers are listed.

rates into two cell types: trophoblast, which will form extra-embryonic tissues like the placenta, and the *inner cell mass*, which gives rise to the embryo proper. The inner cell mass eventually forms three germ layers, each with distinct fates. One layer, the **ectoderm**, will make neural and epidermal cells; another, the **mesoderm**, will make muscle and connective tissue; the third layer, the **endoderm**, will make gut epithelia (Figure 21-3).

Once the three germ layers are established, they subsequently divide into cell populations with different fates. For instance, the ectoderm becomes divided into those cells that are precursors to the skin epithelium and those that are precursors to the nervous system. There appears to be a progressive restriction in the range of cell types that can be formed from stem cells and precursor cells as development proceeds. An early embryonic stem cell, as we've seen, can form every type of cell, an ectodermal cell has a choice between neural and epidermal fates, while a keratinocyte precursor can form skin but not neurons.

Another restriction that occurs early in animal development is the setting aside of cells that will form the **germ line**—the stem cells and precursor cells that eventually will give rise to eggs in a female and sperm in a male. Only the genome of the germ line will ever be passed on to progeny. The setting aside of germ-line cells early in development has been hypothesized to protect chromosomes from damage by reducing the number of rounds of replication they undergo. Whatever the reason, the early segregation of the germ-line is widespread (though not universal) among animals. In contrast, plants do nothing of the sort; meristems, growing tips of roots and shoots, can often give rise to germ-line cells and there is no germ-line lineage set aside early.

One consequence of the early segregation of germ-line cells is that the loss or rearrangement of genes in somatic cells will not affect the inherited genome of a future zygote. Nonetheless, although segments of the genome are rearranged and lost during development of lymphocytes from hematopoietic precursors, most somatic cells seem to have an intact genome, equivalent to that in the germ line (Chapter 24). Evidence that at least some somatic cells have a complete and functional genome comes from the successful production

of cloned animals by *nuclear-transfer cloning*. In this procedure, the nucleus of an adult (somatic) cell is introduced into an egg that lacks its nucleus; the manipulated egg, which contains the diploid number of chromosomes and is equivalent to a zygote, then is implanted into a foster mother. The only source of genetic information to guide development of the embryo is the nuclear genome of the donor somatic cell. The frequent failure of such cloning experiments, however, raises questions about how many adult somatic cells do in fact have a complete functional genome. Even the successes, like the famous cloned sheep “Dolly,” often have medical problems. The extent to which differentiated cells harbor fully functional genomes is still not fully understood. A cell could, for example, have an intact genome, but be unable to properly reactivate certain genes due to inherited chromatin states.

These observations raise two important questions: How are cell fates progressively restricted during development? Are these restrictions irreversible? In addressing these questions, it is important to remember that a cell’s capabilities in its normal *in vivo* location may differ from what it is capable of doing if manipulated experimentally. Thus the observed limits to what a cell can do may result from natural regulatory mechanisms or may reflect a failure to find conditions that reveal the cell’s full potential.

Although our focus in this chapter is on how cells become different, their ability to remain the same also is critical to the functioning of tissues and the whole organism. Non-dividing differentiated cells with particular characteristics often retain these features for many decades. Stem cells that divide regularly, such as a skin stem cell, must produce one daughter cell with the properties of the parental cell, retaining its characteristic composition, shape, behavior, and responses to specific external signals. Meanwhile, the other daughter cell, with its own distinct inheritance as the result of asymmetric cell division, embarks on a particular differentiation pathway, which may be determined both by the signals the cell receives and by

intrinsic bias in the cell’s potential, such as the previous activation of certain genes.

The Complete Cell Lineage of *C. elegans* Is Known

In the development of some organisms, cell lineages are under tight genetic control and thus are identical in all individuals of a species. In other organisms the exact number and arrangement of cells vary substantially among different individuals. The best-documented example of a reproducible pattern of cell divisions comes from the nematode *C. elegans*. Scientists have traced the lineage of all the somatic cells in *C. elegans* from the fertilized egg to the mature worm by following the development of live worms using Nomarski differential interference contrast (DIC) microscopy (Figure 21-4).

About 10 rounds of cell division, or fewer, create the adult worm, which is about 1 mm long and 70 μm in diameter. The adult worm has 959 somatic cell nuclei (hermaphrodite form) or 1031 (male). The number of somatic cells is somewhat fewer than the number of nuclei because some cells contain multiple nuclei (i.e., they are syncytia). Remarkably, the pattern of cell divisions starting from a *C. elegans* fertilized egg is nearly always the same. As we discuss later in the chapter, many cells that are generated during development undergo programmed cell death and are missing in the adult worm. The consistency of the *C. elegans* cell lineage does not result entirely from each newly born cell inheriting specific information about its destiny. That is, their birth cells are not necessarily “hard wired” by their own internal inherited instructions to follow a particular path of differentiation. In some cases, various signals direct initially identical cells to different fates, and the outcomes of these signals are consistent from one animal to the next.

The first few cell divisions in *C. elegans* produce six different *founder cells*, each with a separate fate as shown in

Video: *C. elegans* Crawling

▲ **FIGURE 21-4** Newly hatched larva of *C. elegans*. Some of the 959 somatic-cell nuclei in the hermaphrodite form are visualized in this micrograph obtained by differential interference

contrast (DIC) microscopy, sometimes called Nomarski microscopy. The most easily seen are the intestinal nuclei, which appear as round discs. [From J. E. Sulston and H. R. Horvitz, 1977, *Devel. Biol.* **56**:110.]

Figure 21-5a, b. The initial division is asymmetric, giving rise to P1 and the AB founder cell. Further divisions in the P lineage form the other five founder cells. Some of the signals controlling division and fate asymmetry are known. For example, Wnt signals from the P2 precursor control the asymmetric division of the EMS cell into E and MS founder cells. Wnt signaling (see Figure 16-32) is also used in other asymmetric divisions in worms. Some of the embryonic cells function as stem cells, dividing repeatedly to form more of themselves or another type of precursor cell, while also generating differentiated cells that give rise to a particular tissue. The complete lineage of *C. elegans* is shown in Figure 21-5c. This

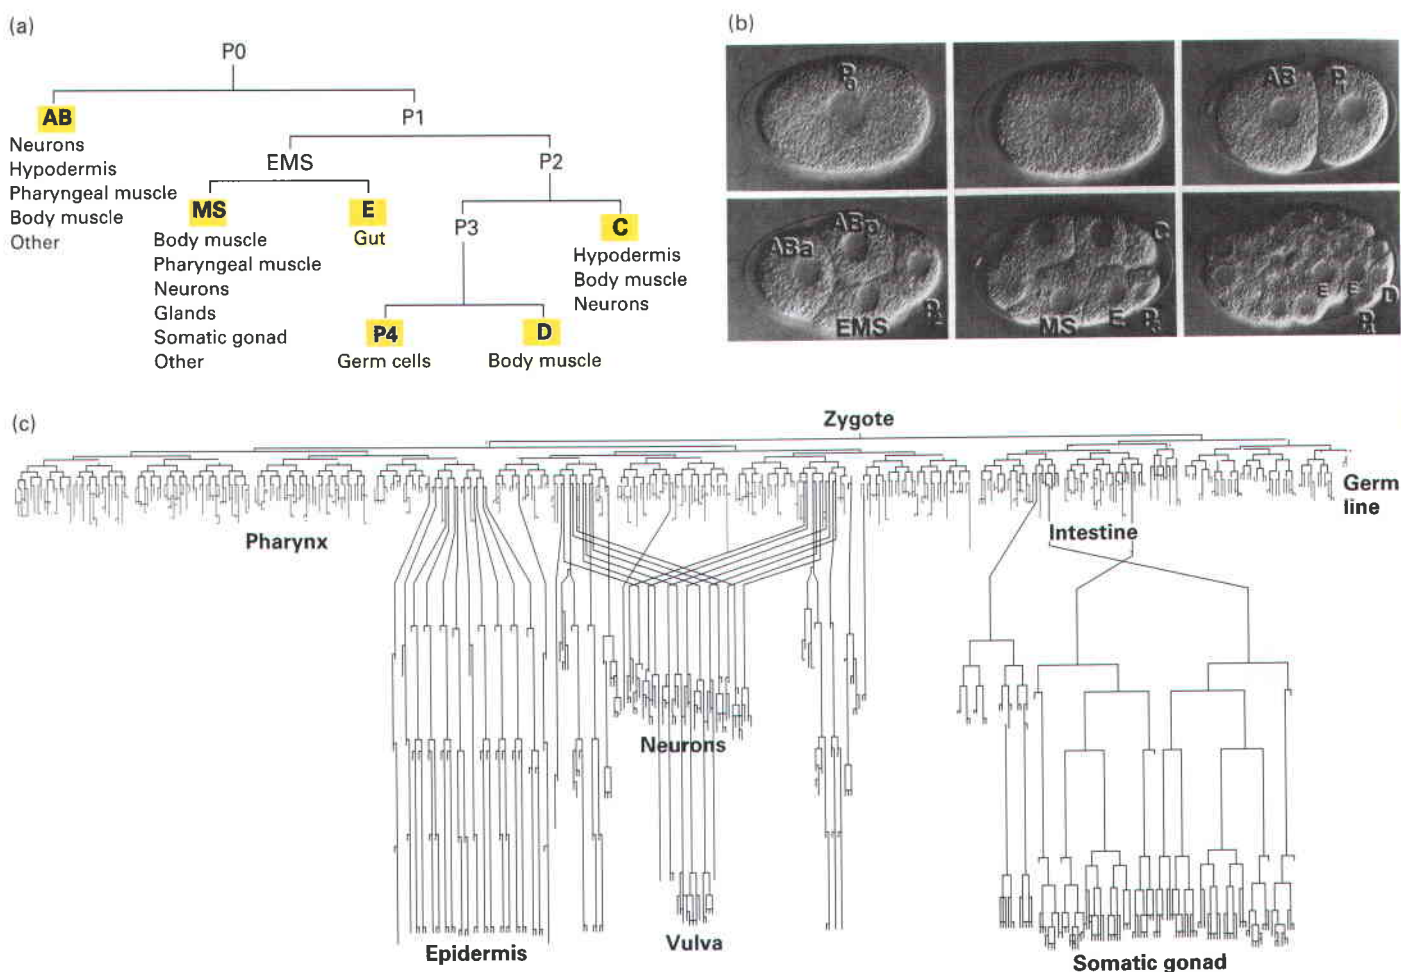

organism has been a powerful model system for genetic studies to identify the regulators that control cell lineages in time and space.

Heterochronic Mutants Provide Clues About Control of Cell Lineage

Intriguing evidence for the genetic control of cell lineage has come from isolation and analysis of *heterochronic mutants*. In these mutants, a developmental event typical of one stage of development occurs too early (precocious development) or too late (retarded development). An example of the

Video: Time-Lapse Imaging of *C. elegans* Embryogenesis

▲ **FIGURE 21-5 *C. elegans* lineage.** (a) Pattern of the first few divisions starting with P0 (the zygote) and leading to formation of the six founder cells (yellow highlight). The first division is asymmetric, producing P1 and AB, a founder cell. Further divisions in the P lineage generate the other five founder cells. Note that more than one lineage can lead to the same tissue type (e.g., muscle or neurons). The EMS cell is so named because it is the precursor to most of the endoderm and mesoderm. The lineage beginning with the P4 cell gives rise to all of the germ-line cells, which are set aside

very early, as in most animals. All the other lineages give rise to somatic cells. (b) Light micrographs of the first few divisions of the embryo that generate the founder cells with cells labeled as in part (a). The texture of the cells shows the presence of organelles. (c) Full lineage of the entire body of the worm, showing some of the tissues formed. Note that any particular cell undergoes relatively few divisions, typically fewer than 15. [Part (b) from Einhard Schierenberg Zoologisches Institut, Universität Köln.]

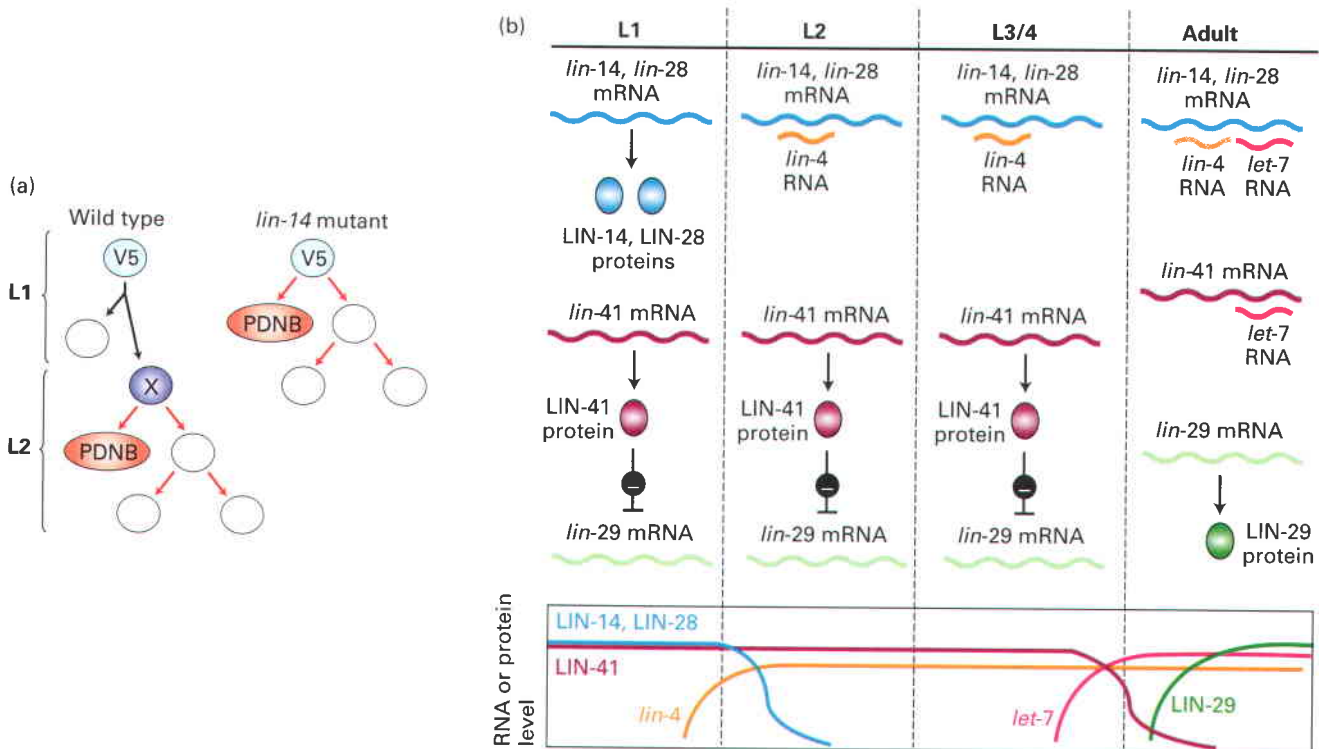

former is premature occurrence of a cell division that yields a cell that differentiates and a cell that dies; as a result, the lineage that should have followed from the dead cell never happens. An example of the latter is the delayed occurrence of a lineage, causing juvenile structures to be produced, incorrectly, in more mature animals. In both cases, the character of a parental cell is, in essence, changed to the character of a cell at a different stage of development.

The study of heterochronic genes has been important to understanding the mechanisms of development and gene regulation. One example of precocious development in *C. elegans* comes from loss-of-function mutations in the *lin-14* gene, which cause premature formation of a certain neural precursor, the PDNB neuroblast (Figure 21-6a). The *lin-14* gene and several others found to be defective in heterochronic worm mutants encode RNA-binding or DNA-binding proteins, which presumably coordinate expression of other genes.

Two other genes (*lin-4* and *let-7*) discovered in heterochronic *C. elegans* mutants were initially puzzling because they appeared to encode small RNAs that do not encode any

protein. To discover the products of these genes, scientists first determined which pieces of genomic DNA could restore gene function, and therefore proper cell lineage, to mutants defective in each gene. They then did the same thing with genomic DNA from the corresponding genomic regions of different species of worm. Comparison of the “rescuing” fragments from the different species revealed that they shared common short sequences with little protein-coding potential.

The short RNA molecules encoded by *lin-4* and *let-7* were subsequently shown to inhibit translation of the mRNAs encoded by *lin-14* and other heterochronic genes (Figure 21-6b). These small RNAs, called **micro RNAs (miRNAs)**, are produced by RNA polymerase II and are complementary to sequences in the 3' untranslated parts of target mRNAs. The miRNAs direct post-transcriptional silencing of mRNAs by hybridizing to them and blocking translation or stimulating degradation (see Figure 8-25). Temporal changes in the production of *lin-4*, *let-7*, and other miRNAs during the life cycle of *C. elegans* serve as a regulatory clock for cell lineage.

▲ FIGURE 21-6 Timing of cell divisions during development of *C. elegans*. (a) The pattern of cell division for the V5 cell of *C. elegans* is shown for normal (wild-type) worms and for a heterochronic mutant called *lin-14*. In the *lin-14* mutant, the pattern of cell division (red arrows) that normally occurs only in the second larval stage (L2) occurs in the first larval stage (L1), causing the PDNB neuroblast to be generated prematurely. In the mutant, the V5 cell behaves during L1 like cell “X” (purple) normally does in L2. The inference is that the LIN-14 protein prevents L2-type cell divisions, although precisely how it does so is unknown. (b) Two small regulatory RNAs, *lin-4* and *let-7*, serve as coordinating timers of gene expression. Binding of the *lin-4*

RNA to the 3' untranslated regions (UTRs) of *lin-14* and *lin-28* mRNAs prevents translation of these mRNAs into protein. This occurs following the first larval (L1) stage, permitting development to proceed to the later larval stages. Starting in the fourth larval stage (L4), production of *let-7* RNA begins. It hybridizes to *lin-14*, *lin-28*, and *lin-41* mRNAs, preventing their translation. LIN-41 protein is an inhibitor of translation of the *lin-29* mRNA, so the appearance of *let-7* RNA allows production of the *lin-29* protein, which is needed for generation of adult cell lineages. LIN-4 may also bind to *lin-41* RNA at later stages. Only the 3' UTRs of the mRNAs are depicted. [Adapted from B. J. Reinhart et al., 2000, *Nature* 403:901.]

miRNAs have been identified in many other animals including vertebrates and insects. More than 300 are encoded in the human genome, perhaps as many as a thousand. Since production of miRNAs is temporally and spatially regulated, they are likely to control a broad range of events, perhaps including timed events as in *C. elegans*. How production of these regulatory miRNAs is temporally controlled is not yet known, but they have turned out to play many roles in regulating gene expression (Chapter 8).

Cultured Embryonic Stem Cells Can Differentiate into Various Cell Types

Embryonic stem (ES) cells can be isolated from early mammalian embryos and grown in culture (Figure 21-7a). Cultured ES cells can differentiate into a wide range of cell types, either in vitro or after reinsertion into a host embryo. When grown in suspension culture, human ES cells first differentiate into multicellular aggregates, called *embryoid bodies*, which resemble early embryos in the variety of tissues they form. When these are subsequently transferred to a solid medium, they grow into confluent cell sheets containing a variety of differentiated cell types including neural cells and pigmented and non-pigmented epithelial cells (Figure 21-7b).

Under other conditions, ES cells have been induced to differentiate into precursors for various types of blood cells. What properties give ES cells their remarkable plasticity? A variety of actors play a role: signaling proteins, DNA methylation, micro RNAs, transcription factors, and chromatin regulators can all affect which genes become active (Chapters 7 and 8).

During the earliest stages of embryogenesis, as the fertilized egg begins to divide, both the paternal and maternal DNA becomes demethylated (see the discussion of DNA methylation in Chapter 7). This happens because a key maintenance methyltransferase (Dnmt1), which normally is present in the nucleus, is transiently excluded from the nucleus. During the first few cell divisions the pattern of methylation is reset, erasing earlier epigenetic marking of the DNA and creating a condition where cells have greater potential for diverse pathways of development. Mice engineered to lack Dnmt1 die as early embryos with drastically undermethylated DNA. ES cells prepared from such embryos are able to divide in culture, but in contrast to normal ES cells cannot undergo in vitro differentiation.

The properties of mouse ES cell are critically dependent on the action of three transcription factors produced shortly after fertilization: Nanog, Sox2, and Oct4. The genes that are bound by these factors have been identified using chromatin

◀ EXPERIMENTAL FIGURE 21-7

Embryonic stem (ES) cells can be maintained in culture and can form differentiated cell types.

(a) Human blastocysts are grown from cleavage-stage embryos produced by in vitro fertilization. The inner cell mass is separated from the surrounding extra-embryonic tissues and plated onto a layer of fibroblast cells that help to nourish the embryonic cells. Individual cells are replated and form colonies of ES cells, which can be maintained for many generations and can be stored frozen. (b) In suspension culture, human ES cells differentiate into multicellular aggregates called embryoid bodies (top). After embryoid bodies are transferred to a gelatinized solid medium, they differentiate further into confluent cell sheets containing a variety of differentiated cell types including neural cells (middle), and pigmented and nonpigmented epithelial cells (bottom). [Parts (a) and (b) adapted from J. S. Odorico et al., 2001, *Stem Cells* 19:193.]

immunoprecipitation experiments (see Figure 7-37). Each protein is found at more than a thousand chromosome locations. At about 350 locations, all three proteins are found. DNA microarrays have revealed which genes are active in ES cells. About half of the 350 loci where all three transcription factors accumulate are at or near genes that are transcribed in ES cells. The target genes regulated by these transcription factors encode a wide variety of proteins, including the Oct4, Nanog, and Sox2 proteins themselves, signaling components of the BMP and JAK/STAT pathways, and chromatin factors.

Chromatin regulators that control gene transcription (Chapter 7) are also important in ES cells. In *Drosophila*, polycomb group proteins form complexes that maintain gene repression states that have been previously established by DNA-binding transcription factors. Two mammalian protein complexes related to the fly Polycomb proteins, PRC1 and PRC2, are produced in ES cells. Early mouse embryos lacking components of PRC2 have abnormal development of the inner cell mass (the embryo proper), and ES cells cannot be made from embryos lacking PRC2 functions. The PRC2 complex of proteins acts by adding methyl groups to lysine 27 of histone H3, thus altering chromatin structure to repress genes. Remember that this type of regulation is distinct from methylation of DNA.

 The possibility of using stem cells therapeutically to restore or replace damaged tissue is fueling much research on how to recognize and culture these remarkable cells from embryos and from various tissues in postnatal (adult) animals. For example, if neurons that produce the neurotransmitter dopamine could be generated from stem cells grown in culture, it might be possible to treat people with Parkinson's disease who have lost such neurons. For such an approach to succeed, a way must be found to direct a population of embryonic or other stem cells to form the right type of dopamine-producing neurons, and rejection by the immune system must be prevented. One way to prevent immune rejection is to use adult stem cells from a patient to produce therapeutic cells for that same patient. This is exactly what is done at present in some bone marrow transplants, as we shall see below. However it is not yet possible to isolate adult stem cells with similar capabilities for most other tissues. In animal experiments, embryonic stem cells have proven considerably more adept than adult stem cells at forming a variety of tissues. One approach for exploiting the advantages of ES cells while reducing immunological rejection may be to insert a nucleus from a patient into the environment of an embryonic cell, replacing the endogenous nucleus with one that will confer patient-specific properties upon the cells. Lines of cells that would be accepted by particular patients could then be established. Stem cells grown from blastocysts in this way may become an option for treating Parkinson's disease and perhaps other neurodegenerative conditions such as Alzheimer's disease.

Recent work has been directed at exploring whether embryonic or adult stem cells can be induced to differentiate into cell types that would be useful therapeutically. For example, mouse ES cells have been treated with inhibitors of phosphatidylinositol-3 kinase, a regulator in one of the

phosphoinositide signaling pathways (Chapter 16). The treated ES cells differentiate into cells that resemble pancreatic β cells in their production of insulin, their sensitivity to glucose levels, and their aggregation into structures reminiscent of pancreas structures. Implantation of these differentiated cells into diabetic mice restored their growth, weight, glucose levels, and survival rates to normal. Many important questions must be answered before the feasibility of using human stem cells for such purposes can be assessed adequately. ■

Apart from their possible benefit in treating disease, ES cells have already proven invaluable for producing mouse mutants useful in studying a wide range of diseases, developmental mechanisms, behavior, and physiology. By techniques described in Chapter 5, it is possible to eliminate or modify the function of a specific gene in ES cells (see Figure 5-40). Then the mutated ES cells can be employed to produce mice with a **gene knockout** (see Figure 5-41). Analysis of the effects caused by deleting or modifying a gene in this way often provides clues about the normal function of the gene and its encoded protein.

We will now examine the properties and regulation of some postnatal (adult) stem cells, descendants of ES cells, that build the various organs and tissues in animals.

Adult Stem Cells for Different Animal Tissues Occupy Sustaining Niches

Many differentiated cell types are sloughed from the body or have life spans that are shorter than that of the organism. Disease and trauma also can lead to loss of differentiated cells. Since differentiated cells generally do not divide, they must be replenished from nearby stem-cell populations. Postnatal (adult) animals contain stem cells for many tissues including the blood, intestine, skin, ovaries and testes, muscle, and liver. Even some parts of the adult brain, where little cell division normally occurs, have a population of stem cells. In muscle and liver, stem cells are most important in healing, as relatively little cell division occurs in the adult tissues at other times.

Stem cells need the right microenvironment to maintain themselves. In addition to intrinsic regulatory signals—like the presence of certain regulatory proteins—stem cells rely on extrinsic regulatory signals from surrounding cells to maintain their status as stem cells. The location where a stem-cell fate can be maintained is called a *stem-cell niche* by analogy to an ecological niche, which is a location that supports the existence and competitive advantage of a particular organism. The right combination of intrinsic and extrinsic regulation, imparted by a niche, will create and sustain a population of stem cells.

In order to investigate or use stem cells, they must be found and characterized. It is often difficult to identify stem cells precisely because they may lack distinctive shapes or gene expression. Much of the time, many stem cells do not divide particularly rapidly, being held in reserve, dividing slowly if at all, until stimulated by signals that convey the need for new cells. For example, an inadequate oxygen

supply can stimulate blood stem cells to divide, and injury to the skin can stimulate regenerative cell division starting with the activation of stem cells. Some stem cells, however, including those that form the continuously shed epithelium of the intestine, are continuously dividing, usually at a slow rate.

One approach for identifying stem cells in a mixed cell population depends on their relatively slow rate of division. In this approach, a type of **pulse-chase** experiment, cells are provided with a brief pulse of labeled DNA precursors, such as bromodeoxyuridine (BrdU), then later examined to see which cells are labeled. After the BrdU pulse, cells that are not dividing will not be labeled at all, and rapidly dividing cells will dilute the BrdU label with normal unlabeled nucleotides (the chase). Stem cells, in contrast, will incorporate BrdU during their slow division process. Since they divide relatively rarely, stem cells will retain the BrdU label longer than most other cells, marking them as **label-retaining cells**. This sort of label retention is often a useful way to identify stem cells.

Germ-line Stem Cells The germ line is the line of cells that produces oocytes and sperm. It is distinct from the somatic cells that make all the other tissues but are not passed on to progeny. The germ line, like somatic-cell lineages, has stem cells. Stem-cell niches have been especially well defined in studies of germ-line stem cells in *Drosophila* and *C. elegans*. Germ-line stem cells are present in adult flies and worms and the location of the stem cells is well known. The stem cells were identified by BrdU label retention.

► **FIGURE 21-8 *Drosophila* germarium and the signals that create its stem-cell niches.** (a) Cross-section of the germarium showing female germ-line stem cells (yellow) and some somatic stem cells (gold) in their niches and the progeny cells derived from them. The germ-line stem cells produce cytodblasts (green), which differentiate into oocytes; the somatic stem cells produce follicle cells (brown) that will make the eggshell. The cap cells (dark green) create and maintain the niche for germ-line stem cells, while the inner sheath cells (blue) produce the niche for somatic stem cells. (b) Signaling pathways that control the properties of germ-line stem cells. The signaling molecules—the TGF β proteins Dpp and Gpp as well as Hh—are produced by cap cells. Binding of these ligands to receptors on the surface of a stem cell results in repression of the *bam* gene by two transcription factors, Mad and Med. Repression of *bam* allows germ-line stem cells to renew, whereas activation of *bam* promotes differentiation. Two surface proteins, Arm and Zpg, which physically link cap cells and stem cells, are also important in maintaining the stem-cell niche. Cells out of reach of Arm and Zpg differentiate rather than renew. Micro RNAs are increasingly recognized as critical regulators of cell differentiation, including germ-line cells. Some of them bind to the Piwi protein, an essential germ-line regulator in both cap and stem cells. (c) Signaling pathways that control the properties of somatic stem cells. The Wnt signal Wingless (Wg) is produced by the inner sheath cells and is received by the Frizzled receptor (Fz) on a somatic stem cell. Hh is similarly produced, and is received by the Ptc receptor. Both receptors signal to control transcription resulting in self-renewal of somatic stem cells. [Adapted from L. Li and T. Xie, 2005, *Ann. Rev. Cell Devel. Biol.* **21**:605.]

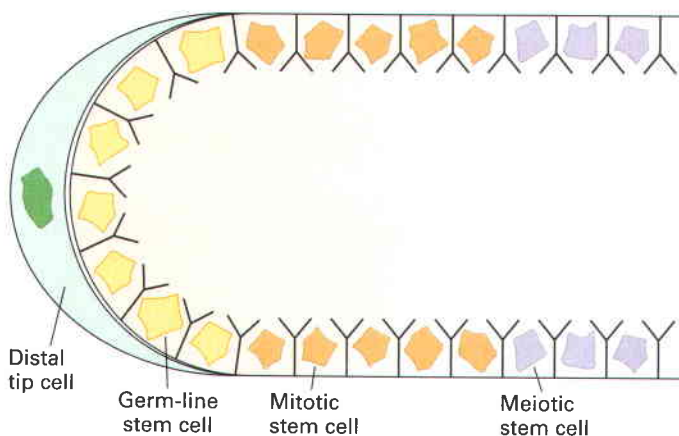

In the fly ovary, the niche where oocyte precursors form and begin to differentiate is located next to the tip of the *germarium* (Figure 21-8a). There are two or three germ-line stem cells in this location next to a few cap cells, which create the niche by secreting two **transforming growth factor β (TGF β)** proteins (Dpp and Gbb) and **Hedgehog (Hh)** protein (Figure 21-8b). These secreted protein signals were introduced in Chapter 16. When the stem cells divide, they produce two daughters, one of which remains adjacent to the cap cells and is therefore a stem cell like the mother cell. The other daughter divides to produce two cytodblast cells that will differentiate into germ-line cells. The cytodblast cells embark on a path of differentiation because they are too far from the cap cells to receive the cap cell-derived signals, including Hh, Dpp, and Gbb, and direct cell-cell

interactions mediated by the cell-surface proteins Arm and Zpg, which together direct a cell to remain a stem cell. Both cap cells and germ-line stem cells produce Piwi proteins, which bind micro RNAs. Piwi proteins and their bound miRNAs regulate gene expression and control germ-line cell development in a wide variety of animals as well as stem-cell development in plants. Thus they constitute an ancient mechanism of developmental regulation. Separate somatic stem cells in the germarium produce follicle cells that will make the eggshell. The somatic stem cells have a niche too, created by the inner sheath cells, which produce Wingless (Wg) protein—a fly Wnt signal—and Hh protein (Figure 21-8c). Thus two different populations of stem cells can work in close coordination to produce different parts of an egg.

Micro RNAs control the division properties of *Drosophila* female germ-line stem cells. The Dicer protein, a double-stranded RNase, produces micro RNAs (see Figure 8-25). Germ-line stem cells with *dicer* mutations fail to pass successfully through the G₁ to S transition of the cell cycle; as a result, the population of stem cells and therefore oocytes is depleted. The absence of miRNA function causes, directly or indirectly, increased function of the p21/27 cyclin-dependent kinase inhibitor. As discussed in Chapter 20, p21/27 normally restricts G₁ to S transitions by regulating cyclin E-CDK complexes. Thus the net effect of the absent miRNA function, which permits increased p21/27 activity, is to restrict cell division.

In worms the long tubelike arms of the gonads have tips where a cell called a distal tip cell creates a stem-cell niche (Figure 21-9). The transmembrane protein Delta, produced by the distal tip cell, binds to the Notch receptor on the

▲ **FIGURE 21-9** *C. elegans* germ-line stem-cell niche. A cross-section of the tip of a gonad arm shows stem cells in their niche and progeny derived from them. The single distal tip cell (green) in each gonad arm creates and maintains the niche. Self-renewing mitotic stem cells produced by the germ-line stem cells convert to meiosis when they move beyond the range of the Delta signal from the distal tip cell. During these stages, the cells are only partially separated by membranes (“Y” shapes) and are therefore a syncytium. [Adapted from L. Li and T. Xie, 2005, *Ann. Rev. Cell Devel. Biol.* **21**:605.]

germ-line stem cells. The Delta/Notch signaling pathway (see Figure 16-36) promotes mitotic division of worm germ-line stem cells, thus creating more stem cells. Meiosis (i.e., germ-line differentiation) is blocked by the Delta signal until the stem cells move beyond the range of the signal from the distal tip cell. Mutations that activate Notch in the germ-line stem cells, even in the absence of Delta signal, cause a gonadal tumor with massive numbers of extra germ-line stem cells, due to excessive mitosis and little meiosis.

The identification and characterization of *Drosophila* and *C. elegans* germ-line stem cells were important because they showed convincingly the existence of stem-cell niches and permitted experiments to identify the niche-made signals that cause cells to become and remain stem cells. Thus a stem-cell niche is a set of cells and the signals they produce, not just a location. Identification of specific molecules that maintain the stem-cell state in *Drosophila* and *C. elegans* brought an unexpected bonus: Some of these molecules are also used to form a stem-cell niche and control stem-cell fates in mammals. For example, germ-line stem cells in the mouse testis are dependent on a TGFβ signaling protein (GDNF) derived from somatic cells. Each seminiferous tubule contains exactly one germ-line stem cell, which divides asymmetrically to re-create itself and to produce a spermatogonial cell. This cell proliferates and its progeny become spermatocytes, which go through the extraordinary differentiation process that builds a sperm. The niche is created by a specialized region of the Sertoli cell along with a myoid cell and a basement membrane produced by the myoid cell, though many details of the molecular signals remain to be explored.

Skin/Hair Stem Cells in Mammals Epithelial stem cells that give rise to skin and hair in mammals are located in hair follicles and in the basal layer of the epithelium between follicles. In the hair follicle, the stem cells occupy a niche called the *bulge* (Figure 21-10a). The stem cells divide asymmetrically to produce more stem cells and to make precursor cells of at least two kinds. One type of precursor will rise toward the surface of the skin and form *keratinocytes*, the major cell type of skin, which is a multilayered epithelium (the epidermis). Other cells emerge from the stem cells to become hair-matrix progenitors that move down deeper in the hair follicle and form a complex set of structures including the hair itself.

The molecular regulators in the skin stem-cell niche are incompletely known. However, as in flies, TGFβ signals, arising from mesenchymal cells that surround the bulge cells, and a Wnt signal, arising from the dermal papilla, are important in controlling stem-cell renewal and differentiation into either skin or hair (Figure 21-10b). Evidence for the importance of Wnt signaling came from manipulations of the expression of *β-catenin*, a protein that helps link certain cell-cell junctions to the cytoskeleton (see Figure 19-12) and also functions as a signal transducer in the

▲ FIGURE 21-10 Skin/hair stem-cell niche in mammals and the signals that control it. (a) A hair follicle showing stem cells (yellow) in the bulge and interfollicular stem cells (light green) among the basal epithelial cells (green) outside the hair follicle. The progeny of bulge stem cells migrate down to contribute to hair formation near the dermal papilla. The dark green cells have yet to begin terminal differentiation; they are transient amplifying cells that are still dividing but cannot generate stem cells. Note that only the basal layer of epithelial cells adjacent to the basement membrane are shown. Overlaying these basal cells, outside of the follicle, are several layers of differentiating keratinocytes. (b) Signaling events in the stem-cell niche. The source of each signal is indicated in parentheses. A Wnt signal promotes formation of new hair cells, but in the bulge—home of the stem cells—at least three Wnt inhibitors (Dkk, Wif, and sFRP) block differentiation and preserve the stem-cell state. Away from those inhibitors, the lack of Wnt signaling allows differentiation of stem cells into skin cells (keratinocytes). BMP, which belongs to the TGF β family of signaling proteins, is produced by mesenchymal cells adjacent to the bulge. During development, when new hair is to be grown, the dermal papilla makes Noggin, which blocks the BMP signal, and more Wnt, which overcomes the inhibitors, allowing stem cells to differentiate into hair cells. BMPs have complex and incompletely understood roles in skin development, and their functions change with the stage of development. [Adapted from F. M. Watt et al., 2006, *Curr. Opin. Genet. Devel.* **16**:518, and L. Li and T. Xie, 2005, *Ann. Rev. Cell Devel. Biol.* **21**:605.]

Wnt pathway (see Figure 16-32). Activation of β -catenin changes the fate of cells from epidermis (skin) to hair. In contrast, removal of β -catenin from the skin of engineered mice eliminates formation of hair cells. Epithelial stem cells then form only epidermis, not hair cells. Thus β -catenin acts as a switch that controls which type of precursor arises from epithelial stem cells. Wnt signals also have stimulatory effects on cell division, which can be

restrained by Wnt pathway inhibitors, such as DKK and sFRP, that are present in the bulge—a Battle of the Bulge of sorts.

Newly formed keratinocytes move toward the outer surface, becoming increasingly flattened and filled with keratin intermediate filaments (Chapter 18). It normally takes about 15–30 days for a newly “born” keratinocyte in the lowest layer of the skin to differentiate and move to the topmost layer. The “cells” forming the topmost layer are actually dead and are continually shed from the surface.

■ In addition to keratinocytes, skin contains dendritic epidermal T cells, an immune-system cell that produces a certain form of the T-cell receptor (Chapter 24). When dendritic epidermal T cells are genetically modified so they do not produce T-cell receptors, wound healing is slow and less complete than in normal skin. Normal healing is restored by addition of keratinocyte growth factor. The current hypothesis is that when dendritic epidermal T cells recognize antigens on cells in damaged tissue, they respond by producing stimulating proteins, such as keratinocyte growth factor, that promote the production of more keratinocytes and wound healing. Many other signals—including Hedgehog, calcium, and transforming growth factor α (TGF α)—control the production of skin cells from stem cells. Discovering how all these signals work together to control growth and stimulate healing will advance our understanding of diseases such as psoriasis and skin cancer and perhaps pave the way for effective treatments. **■**

Intestinal Stem Cells In contrast to epidermis, the epithelium lining the small intestine is a single cell thick (see Figure 19-8). This thin layer is enormously important for keeping toxins and pathogens from entering our bodies; it also transports nutrients essential for survival from the intestinal lumen into the body (see Figure 11-29). The cells of the intestinal epithelium continuously regenerate from a stem-cell population located deep in the intestinal wall in pits called *crypts* (Figure 21-11a). By identifying the label-retaining cells in the intestinal epithelium, researchers determined that the stem cells are located precisely four or five cells above the bottom of a crypt. The niche is created by mesenchymal cells that abut the crypts at the level of the stem cells. These cells produce a Wnt signal, a BMP (TGF β) signal, and possibly a ligand for the Notch receptor on stem cells (Figure 21-11b). Overproduction of β -catenin in intestinal cells leads to excess proliferation of those cells, as though they were receiving too much Wnt signal (which stabilizes β -catenin). Blocking the function of β -catenin by interfering with the TCF transcription factor that it activates abolishes the stem cells in the intestine. Thus Wnt signaling, acting through β -catenin, plays a critical role in maintaining the intestinal stem-cell population. BMP has the opposite effect, promoting differentiation and restraining the effect of Wnt.

◀ **FIGURE 21-11 Intestinal stem-cell niche and the signals that control it.** (a) Finger-like projections of the inner surface of the intestine called villi are divided by deep pits called crypts. The single-cell thick epithelium protects us from infection and allows selective transport of useful nutrients into the blood stream. (b) An intestinal crypt showing the intestinal stem cells (yellow), their proliferating mitotic progeny (light green), and precursors (dark green) in the final stages of differentiation. Mesenchymal cells, shown in blue, create this stem-cell niche. Paneth cells (orange), located at the base of the crypt, secrete antimicrobial defense proteins called defensins. These proteins form pores in bacterial membranes, leading to death of the bacteria. Signaling events in the stem-cell niche. Wnt signals promote stem-cell fates, offsetting BMP signals that push toward differentiation. Noggin restrains the BMP signals and thus promotes stem-cell proliferation, whereas Dkk restrains Wnt signaling when growth is not needed. The Notch receptor is also involved, although its ligand on mesenchymal cells is unknown. [Adapted from L. Li and T. Xie, 2005, *Ann. Rev. Cell Devel. Biol.* 21:605.]

Intestinal stem cells produce precursor cells that proliferate and differentiate as they ascend the sides of crypts to form the surface layer of the finger-like gut projections called *villi*, across which intestinal absorption occurs. Pulse-chase labeling experiments with BrdU have shown that the time from cell birth in the crypts to the loss of cells at the tip of the villi is only about 2 to 3 days. Thus enormous numbers of cells must be produced continually to keep the epithelium intact. The production of new cells is precisely controlled: too little division would eliminate villi and lead to breakdown of the intestinal surface; too much division would create an excessively large epithelium and also might be a step toward cancer. Indeed, mutations that inappropriately activate Wnt signal transduction are a major contributor to the progression of colon cancer, as we shall see in Chapter 25.

Neural Stem Cells The great interest in the formation of the nervous system and in finding better ways to prevent or treat neurodegenerative diseases has made the characterization of neural stem cells an important goal. The earliest stages of vertebrate neural development involve the rolling up of ectoderm to form the *neural tube*, which extends the length of the embryo from head to tail (Figure 21-12a).

Initially the neural tube is composed of a single layer of cells, the neural stem cells (NSCs); these will give rise to the entire central nervous system (brain and spinal cord). Labeling and tracing experiments have shown where neural cells are born and where they go after birth. The most active region of cell division is the *subventricular zone*, which has the properties of a stem-cell niche and is named for its proximity to the central fluid-filled *ventricle*.

The embryonic neural stem cells that line the ventricle divide can symmetrically, produce two daughter stem cells side-by-side (Figure 21-12b), or asymmetrically, produce a cell that remains a stem cell and another that migrates radially outward. The migrating cells are often transient amplifying (TA) cells, which in turn divide to form neural precursors called neuroblasts. Once formed, TA cells and neuroblasts migrate radially outward and form successive layers of the neural tissue in an inside-out order, whereas the stem cells remain in contact with the ventricle (see Figure 21-12b). Newly formed cells therefore traverse the layers of preexisting cells before taking up residence on the outside.

Tracing experiments with viruses have shown that a neuroblast can produce two daughters, one a neuron and one a glial cell. In these experiments, a library of defective

◀ **FIGURE 21-12 Formation of the neural tube and division of neural stem cells.** (a) Early in development, a portion of the ectoderm rolls up and separates from the rest of the embryonic cells. This forms the epidermis (gray) and the neural tube (blue). Near the interface between the two, neural crest cells form and then migrate to contribute to skin pigmentation, nerve formation, craniofacial skeleton, heart valves, peripheral neurons, and other structures. The notochord, a rod of mesoderm for which we are named (chordates), provides signals that affect cell fates in the neural tube (Chapter 22). The interior of the neural tube will become a series of fluid-filled chambers called ventricles. Neural stem cells located adjacent to the ventricles in the subventricular zone will divide to form neurons that migrate radially outwards to form the layers of the nervous system. (b) Neural stem cells in the subventricular zone can divide symmetrically (*top*), along their apical-basal axis, to give rise to side-by-side daughter stem cells, both in contact with the ventricle. Alternatively, stem cells can divide, along their other axis, to produce one daughter that is a stem cell able to self-renew and a daughter cell, called a transient amplifying (TA) cell, that begins to migrate and differentiate (*bottom*). A key difference between the two patterns of division is the orientation of the mitotic spindle. [Adapted from L. R. Wolpert et al. 2002. *Principles of Development*, 2d ed., Oxford University Press.]

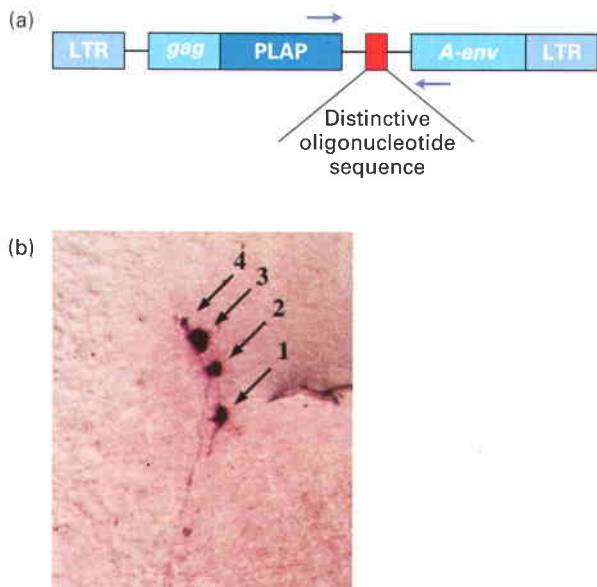

retroviruses, each able to infect only once and containing a unique DNA sequence, was prepared (Figure 21-13a). Any cell infected by a single virion would give rise to a clone of cells that all carry that particular virus' DNA sequence. In this way, all the cells that derived from a single neural stem cell or TA cell can be identified as a clone (Figure 21-13b). The results of these tracing experiments were surprising. First, some neurons were found to have migrated considerable distances laterally, abandoning their radial migration to the outer cortical layer. Second, in some cases, a single neuron and single glial cell, shared the same viral DNA sequence. A neural precursor had evidently been infected and had then divided once to give rise to two quite different cell types.

Most mammalian brain cells stop dividing by adulthood but some cells in the subventricular zone and at least one other part of the brain continue to act as stem cells and generate new neurons (Figure 21-14). In the subventricular zone of adults, the neural stem cells are astrocytes, a somewhat confusing nomenclature since more

traditionally “astrocyte” meant a type of glia cell. Evidently neural stem cells are a subset of astrocytes not previously recognized for their special stem-cell qualities. Neural stem cells have some properties of astrocytes, such as producing glial fibrillary acidic protein (GFAP), but they also can divide asymmetrically to renew themselves and to produce TA cells.

The subventricular stem-cell niche is created by mostly unknown signals from the ependymal cells that form a layer just inside the neural tube (lining the ventricle) and by endothelial cells that form blood vessels in the vicinity (Figure 21-14b). The endothelial cells, and the basal lamina they form, are in direct contact with neural stem cells and are believed to be essential in forming the niche. Each neural stem cell extends a single cilium through the ependymal cell layer to directly contact the ventricle. Though the function of the cilium is unknown, it may function as an antenna for receiving signals that would otherwise be inaccessible to the neural stem cell. The signals that create the niche are not completely characterized, but there is evidence for a blend of factors including FGFs, BMPs, IGF, VEGF, TGF α , and BDNF. The BMPs appear to favor astrocyte differentiation over neural differentiation, and over-expression of IGF (insulin-like growth factor) causes mice to develop with abnormally large brains. Later stages of neural development are discussed in Chapter 23.

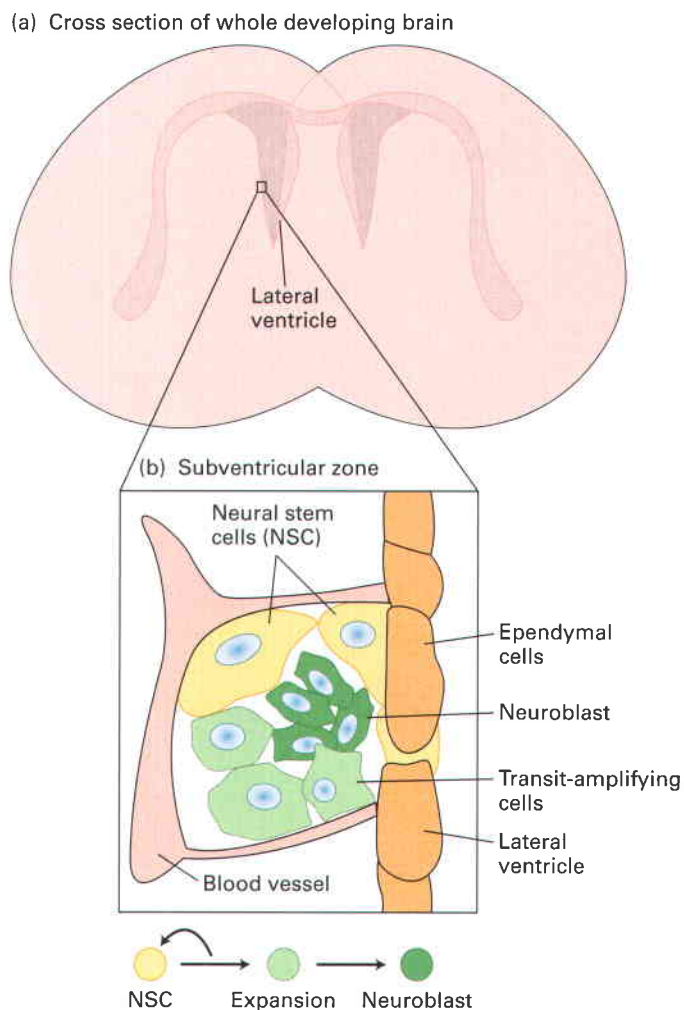

Hematopoietic Stem Cells Like the intestinal epithelium the blood is a continuously replenished tissue. The stem cells

▲ **EXPERIMENTAL FIGURE 21-13** Retrovirus infection can be used to trace cell lineage. (a) Engineered viral genome. The long terminal repeats (LTRs) are standard retroviral repeats. Viral proteins required for infection are encoded in the *gag* and in *A-env* genes. PLAP is an introduced gene for an alkaline phosphatase. Detection of this enzyme by histochemical staining is used to determine which cells carry a virus. The oligonucleotide sequence, synthesized by providing random nucleotides, is different in each virus and can be amplified by PCR, using primers for sequences that are in all viruses (purple arrows), and then sequenced. A library of more than 107 distinct viruses was made. Because these viruses lack the genes required for production of new virions in infected cells, each defective virus can infect only once. (b) Tissue section showing cells infected with defective viruses. The DNA from each stained clone of cells can be extracted and amplified by PCR to determine the sequence of the infecting virus. Cells descended from the same initially infected cell will have the same oligonucleotide sequence, whereas separate infection events will give different sequences. [From J. A. Golden et al., 1995, *Proc. Nat'l. Acad. Sci. USA* **92**:5704.]

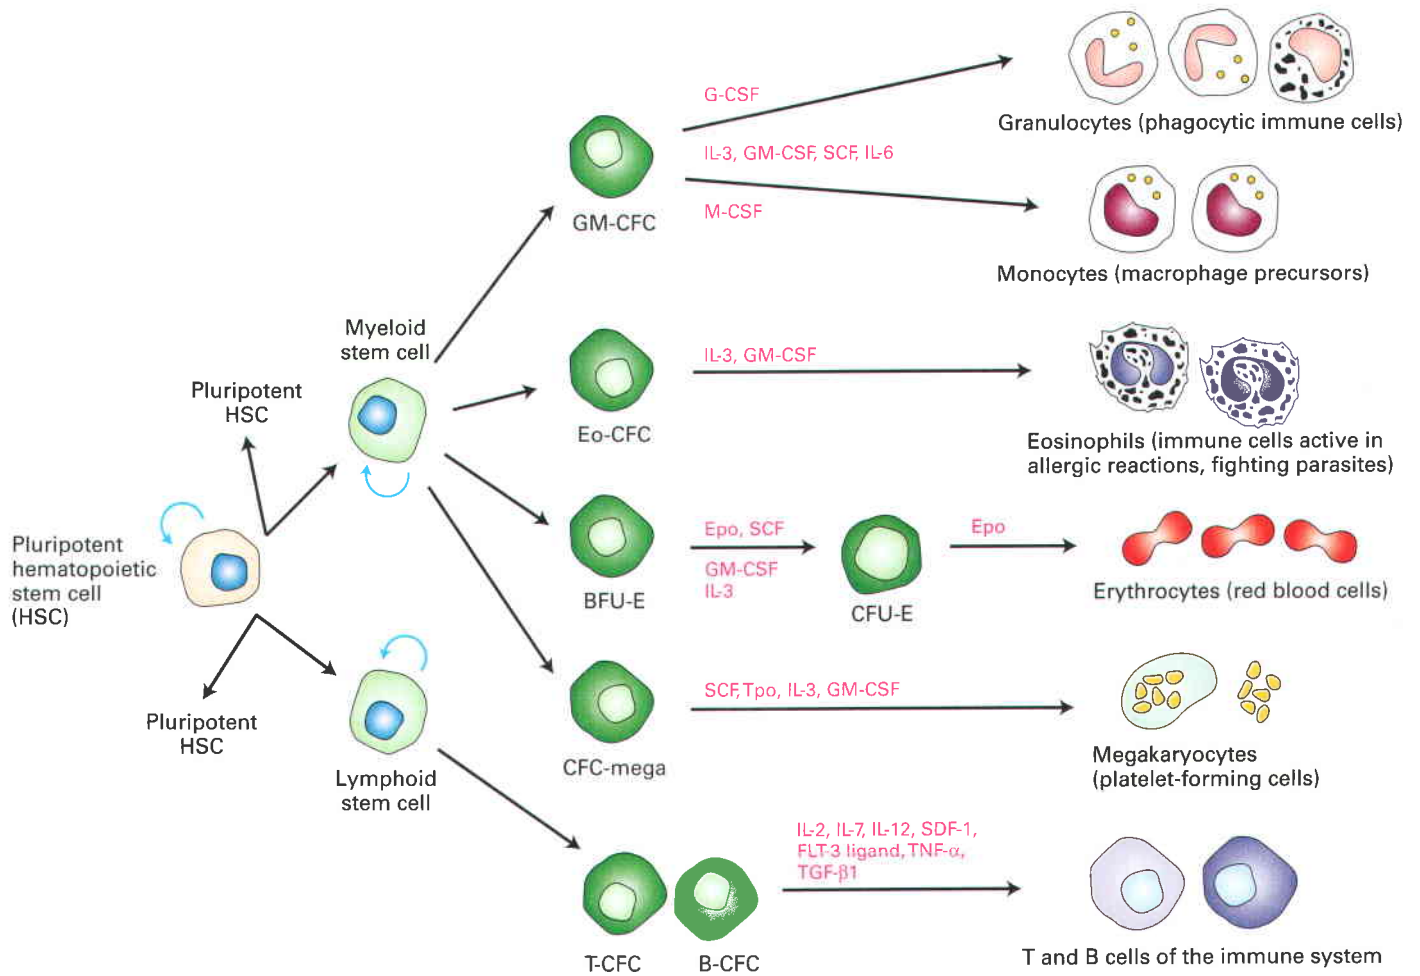

that give rise to the different types of blood cells are located in the bone marrow in adult animals. All types of blood cells derive from a single type of pluripotent *hematopoietic stem cell*, which gives rise to the more-restricted *myeloid* and *lymphoid stem cells* (Figure 21-15). Although myeloid and lymphoid stem cells are capable of self-renewal, each type is committed to one of the two major hematopoietic lineages. Thus these cells function as both stem cells and precursor cells.

After hematopoietic stem cells form, numerous extracellular growth factors called **cytokines** regulate proliferation and differentiation of the precursor cells for various blood-cell lineages. Each branch of the blood-cell lineage tree has different cytokine regulators, allowing exquisite control of the production of specific cells types. For example, after a bleeding injury, when all blood cells are needed, multiple cytokines are produced. But when a

▲ **FIGURE 21-14** Neural stem-cell niche. (a) Cross-section of the developing nervous system showing the lateral ventricle, a fluid-filled space inside the neural tube. The area just surrounding the ventricle, called the subventricular zone, is the site of stem cells from which neural precursors arise. (b) The neural stem cells (yellow), a subset of astrocytes, are in contact with blood vessels (blue) and adjacent ependymal cells (pink), both of which provide signals or direct contacts that maintain the stem-cell population. Neural stem cells (NSC) divide to renew themselves and to form a dividing population of transit amplifying (TA) cells (light green; see Figure 21-12b). TA cells in turn divide to form neuroblasts (dark green), which give rise to neurons. [Adapted from L. Li and T. Xie, 2005, *Ann. Rev. Cell Devel. Biol.* **21**:605.]

person is traveling at high altitude and needs additional erythrocytes, **erythropoietin**—a cytokine that acts only on erythrocyte precursors—is produced. Erythropoietin activates several different intracellular signal-transduction pathways, leading to changes in gene expression that promote formation of erythrocytes (see Figure 16-6). In contrast GM-CSF, a different cytokine, stimulates production of granulocytes, macrophages, eosinophils, and megakaryocytes.

▲ FIGURE 21-15 Formation of blood cells from hematopoietic stem cells in the bone marrow. Pluripotent stem cells (yellow) may divide symmetrically to self-renew (blue curved arrow) or divide asymmetrically to form a myeloid or lymphoid stem cell (light green) and a daughter cell that is pluripotent like the parental cell. Although myeloid and lymphoid stem cells are capable of self-renewal, each type is committed to one of the two major hematopoietic lineages. Depending on the types and amounts of cytokines present, the myeloid and lymphoid stem cells generate different precursor cells (dark green), which are incapable of self-renewal. Precursor cells are called colony-forming cells (CFCs) because of their ability to form colonies containing the differentiated cell types shown at right. The colonies are detected

on the spleen of animals that have had their own hematopoietic cells eliminated and the precursor cells introduced. Further cytokine-induced proliferation, commitment, and differentiation of the precursor cells give rise to the various types of blood cells. Some of the cytokines that support this process are indicated (red labels). GM = granulocyte-macrophage; Eo = eosinophil; E = erythrocyte; mega = megakaryocyte; T = T-cell; B = B-cell; CFU = colony-forming unit; CSF = colony-stimulating factor; IL = interleukin; SCF = stem cell factor; Epo = erythropoietin; Tpo = thrombopoietin; TNF = tumor necrosis factor; TGF = transforming growth factor; SDF = stromal cell–derived factor; FLT-3 ligand = ligand for fms-like tyrosine kinase receptor 3. [Adapted from M. Socolovsky et al., 1998, *Proc. Nat'l. Acad. Sci. USA* **95**:6573.]

The hematopoietic lineage originally was worked out by injecting the various types of precursor cells into mice whose precursor cells had been wiped out by irradiation. By observing which blood cells were restored in these transplant experiments, researchers could infer which precursors (e.g., GM-CFC, BFU-E) or terminally differentiated cells (e.g., erythrocytes, monocytes) arise from a particular type of precursor. Remarkably, a single hematopoietic stem cell is sufficient to restore the entire blood system of an irradiated mouse. The first step in these experiments was to separate the different types of hematopoietic precursors.

This separation is possible because each type of precursor produces unique combinations of cell-surface proteins that can serve as type-specific markers. If bone marrow extracts are treated with fluorochrome-labeled antibodies for these markers, cells with different surface markers can be separated in a fluorescence-activated cell sorter (see Figure 9-28).

The frequency of hematopoietic stem cells is about 1 cell per 10^4 bone marrow cells. Activation of the *Hoxb4* gene in embryonic stem cells drives the formation of hematopoietic stem cells. (As described in Chapter 22, *Hoxb4* also plays a

role in pattern formation along the head-to-tail body axis.) The *Bmi* gene is also required for self-renewal of hematopoietic stem cells, and of neural stem cells as well. This gene encodes a polycomb-type chromatin regulator protein that represses certain genes including some **Hox genes**, a group of developmentally important genes discussed in Chapter 22. *Bmi1* is a component of the PRC1 protein complex that we discussed above in relation to embryonic stem cells. Thus members of the polycomb group of proteins are important in both embryonic and adult stem cells.

Like other stem cells, hematopoietic stem cells are residents of a niche. The niche is formed by spindle-shaped cells on the surface of the bone in the bone marrow. N-cadherin fastens the stem cells to these niche cells. A Delta-like ligand produced by niche cells signals to Notch receptors on the stem cells, and several other growth factor–receptor pairs stimulate their self-renewal and differentiation into myeloid or lymphoid stem cells.

 Stem cells can become cancerous. For example, leukemia is a cancer of the white blood cells. This type of cancer is marked by two types of cells: leukemic tumor cells, which arise from differentiated white blood cells and have limited growth abilities, and the more dangerous leukemic tumor stem cells with unlimited growth abilities. The leukemia tumor stem cells, which are capable of initiating a new tumor on their own, are present in a human tumor about once for every million dividing leukemic cells. Thus the bulk of the leukemic cells are not able to grow a new tumor. Therefore to provide an enduring cure, treatments must ensure the death or limited mitosis of the tumor stem cells. This is particularly challenging because many cancer stem cells divide slowly or not at all for substantial periods, making them selectively *resistant* to chemotherapy drugs and irradiation—both treatments that target rapidly dividing cells.

To date, bone marrow transplants, a treatment for leukemia and other blood disorders, represent the most successful and widespread use of stem cells in medicine. In 1959 a patient with end-stage (fatal) leukemia was irradiated to destroy her cancer cells. She was transfused with bone marrow cells from her identical twin sister, thus avoiding an immune response, and was in remission for three months. This promising beginning led to present-day treatments that can often lead to a complete cure for leukemia.

The stem cells in transplanted bone marrow can generate new, functional blood cells in patients with certain hereditary blood diseases and in cancer patients who have received irradiation and/or chemotherapy. Both chemotherapy and irradiation destroy the bone marrow cells as well as cancer cells. Bone marrow transplants go beyond eliminating cancer cells as done with irradiation. Instead, an immune attack on the leukemic cells can be mounted by the injected donor cells. More than two dozen diseases are now commonly treated with bone marrow transplantation. These include

leukemias and anemias of various types, lymphomas, severe combined immunodeficiency, and certain autoimmune disorders. The effectiveness of bone marrow transplants varies among diseases and patients from minor improvement to full cures. Much research is under way to employ other types of stem cells in the treatment of diseases involving nonblood tissues. ■

You have probably noticed that all the molecular regulators of stem cells are familiar signal proteins rather than dedicated regulators that specialize in stem-cell control. Each type of signal is used repeatedly to control cell fates and proliferation. These are ancient signaling systems, at least a half billion years old, for which new uses have emerged as cells, tissues, organs, and animals have evolved new variations. We will see many more examples of such evolutionary conservation in the next chapter on development.

Meristems Are Niches for Stem Cells in Postnatal Plants

 Stem cells in plants are located in **meristems**, populations of undifferentiated cells found at the tips of growing shoots. Shoot apical meristems (SAMs) produce leaves and shoots as well as more stem cells that constitute the nearly immortal meristems. Meristems can persist for thousands of years in long-lived species such as redwood trees and bristlecone pines. As a plant grows, the cells “left behind” the meristems are encased in rigid cell walls and can no longer grow. SAMs can split to form branches, each branch with its own SAM, or be converted into floral meristems (Figure 21-16). Floral meristems give rise to the four floral organs—sepals, stamens, carpels, and petals—that form flowers. Unlike SAMs, floral meristems are gradually depleted as they give rise to the floral organs.

A meristem is a stem-cell niche, but much remains to be learned about how the niche is created and maintained. Numerous genes have been found to regulate the formation, maintenance, and properties of meristems. Many of these genes encode transcription factors that direct progeny of stem cells down different paths of differentiation. For instance, a hierarchy of regulators, particularly transcription factors, controls the separation of differentiating cells from SAMs as leaves form; similarly, three types of regulators control formation of the floral organs from floral meristems (see Figure 22-36). In both cases, a cascade of gene interactions occurs, with earlier transcription factors causing production of later ones. At the same time, cells are dividing and the differentiating ones are spreading away from their original birth sites. One signal that creates the plant niche is *Zwille/Pinhead*, which encodes a protein related to the *Piwi* protein that supports stem-cell niches in animals (see Figure 21-8). These are “argonaute” family proteins, which repress genes in response to certain small RNA molecules. ■

(a) Regions of shoot apical and floral meristems

(b) Fates of cells in L2 layer

▲ **FIGURE 21-16 Cell fates in meristems of *Arabidopsis*.** (a) In these longitudinal sections, cell nuclei are revealed by staining with propidium iodide, which binds to DNA. *Top*: The shoot apical meristem (SAM) produces shoots, leaves, and more meristem. Flower production occurs when the meristem switches from leaf/shoot production to flower production, concomitant with an increase in the number of meristem cells to form floral meristems (FMs), as shown here. *Middle*: Cells in a SAM exhibit different fates and behaviors. Cells divide rapidly in the peripheral zone (PZ, green) to produce leaves and in the rib zone (Rib, blue) to produce central shoot structures. Cells in the central zone (CZ, red) divide more slowly, producing an ongoing source of meristem and contributing cells to the PZ and Rib. *Bottom*: The layers of the meristem, colored blue, pink and yellow here, are each derived (cloned) from the same precursor cell. Scale bars, 50 μm . (b) Color coding shows the fates of cells in different positions in the L2 layer. The color code does not correspond to that in part (a). [Part (a) from E. Meyerowitz, 1997, *Cell* 88:299; micrographs courtesy of Elliot Meyerowitz. Part (b) after C. Wolpert et al., 2002, *Principles of Development*, 2d ed., Oxford University Press.]

but may have different fates if they are exposed to different external signals (see Figure 21-1).

- Pluripotent stem cells can produce more than one type of descendant cell, including in some cases a stem cell with a more-restricted potential to produce differentiated cell types.
- Embryonic development of *C. elegans* begins with asymmetric division of the fertilized egg (zygote). The lineage of all the cells in adult worms is known and is highly reproducible (see Figure 21-5).
- Short regulatory RNAs (micro RNAs) control the timing of developmental cell divisions by preventing translation of mRNAs whose encoded proteins control cell lineages (see Figure 21-6).
- Cultured embryonic stem cells (ES cells) are capable of giving rise to many kinds of differentiated cell types. They are useful in production of genetically altered mice and offer potential for therapeutic uses. Specific transcription factors and chromatin regulators are important in giving ES cells their unusual properties.
- Stem cells are formed in niches that provide signals to maintain a population of nondifferentiating stem cells. The niche must maintain stem cells without allowing their excess proliferation and must block differentiation.
- Germ-line cells give rise to eggs or sperm. By definition, all other cells are somatic cells.
- Populations of stem cells associated with the gonads, skin, intestinal epithelium and most other tissues regenerate differentiated tissue cells that are damaged or sloughed or become aged (see Figures 21-8–21-11, 21-14).
- In the blood cell lineage, different precursor types form and proliferate under the control of distinct cytokines (see Figure 21-15). This allows the body to specifically induce the replenishment of some, or all, of the necessary types.
- Stem cells are prevented from differentiating by specific controls that operate in the niche. A high level of β -catenin, a component of the Wnt signaling pathway, has been implicated in preserving stem cells in the skin and intestine by directing cells toward division rather than differentiation states.
- Plant stem cells persist for the life of the plant in the meristem. Meristem cells can give rise to a broad spectrum of cell types and structures (see Figure 21-16).

KEY CONCEPTS OF SECTION 21.1

The Birth of Cells: Stem Cells, Niches, and Lineage

- In asymmetric cell division, two different types of daughter cells are formed from one mother cell. In contrast, both daughter cells formed in symmetric divisions are identical

21.2 Cell-Type Specification in Yeast

In the previous section, we saw that stem cells and precursor/progenitor cells produce progeny that embark upon specific differentiation paths. The elegant regulatory mechanisms of differentiation are referred to as *cell-type specification*. Specification usually involves a combination

of external signals with internal signal-transduction mechanisms like those described in Chapters 15 and 16. The transition from an undifferentiated cell to a differentiating one often involves the production of one or a small number of transcription factors. The newly produced transcription factors are powerful switches that trigger the activation (and sometimes repression) of large batteries of subservient genes. Thus an initially modest change can cause massive changes in gene expression that confer a new character on the cell.

Our first example of cell-type specification comes from the budding yeast, *S. cerevisiae*. We introduced this useful unicellular eukaryote way back in Chapter 1 and have encountered it in several other chapters. *S. cerevisiae* forms three cell types: haploid *a* and α cells, and diploid *a*/ α cells. Each type has its own distinctive set of active genes; many other genes are active in all three cell types. In a pattern common to many organisms and tissues, cell-type specification in yeast is controlled by a small number of transcription factors that coordinate the activities of many other genes. Similar regulatory features are found in the responses of higher eukaryotic cells to environmental signals and in the specification and patterning of cells and tissues during development (Chapter 22).

DNA microarray studies have provided a genome-wide picture of the fluctuations of gene expression in the different cell types and different stages of the *S. cerevisiae* life cycle (see Figure 5-29 for an explanation of the DNA microarray technique). Among other things, these studies identified 32 genes that are transcribed at more than twofold higher levels in α cells than in *a* cells. Another 50 genes are transcribed at more than twofold higher levels in *a* cells than in α cells. The products of these 82 genes, which initially are activated by cell-type specification transcription regulators, convey many of the critical differences between the two cell types. The results clearly demonstrate that changes in expression of only a small fraction of the genome, in this case <2 percent of the ≈ 6000 yeast genes, can significantly alter the behavior and properties of cells. Transcription of a much larger number of genes, about 25 percent of the total assayed, differed substantially in diploid cells compared with haploid cells. These differences in expression patterns make sense since *a* and α cells are very similar (hence, expression of relatively few genes differ between them), whereas haploid and diploid cells are quite different.

Mating-Type Transcription Factors Specify Cell Types

Each of the three *S. cerevisiae* cell types expresses a unique set of regulatory genes that is responsible for all the differences among the three cell types. All haploid cells express certain haploid-specific genes; in addition, *a* cells express *a*-specific genes, and α cells express α -specific genes. In *a*/ α diploid cells, diploid-specific genes are expressed, whereas haploid-specific, *a*-specific, and α -specific genes are not. As illustrated in Figure 21-17, three cell type-specific transcription factors ($\alpha 1$, $\alpha 2$, and *a1*) encoded at the *MAT locus* act in combination with a general transcription factor called

▲ **FIGURE 21-17** Transcriptional control of cell type-specific genes in *S. cerevisiae*. The coding sequences carried at the *MAT* locus differ in haploid α and *a* cells and in diploid cells. Three type-specific transcription factors ($\alpha 1$, $\alpha 2$, and *a1*) encoded at the *MAT* locus act with MCM1, a constitutive transcription factor produced by all three cell types, to produce a distinctive pattern of gene expression in each of the three cell types. *a.sg* = *a*-specific genes/mRNAs; $\alpha.sg$ = α -specific genes/mRNAs; *h.sg* = haploid-specific genes/mRNAs.

MCM1, which is expressed in all three cell types, to mediate cell type-specific gene expression in *S. cerevisiae*. Thus the actions of just three transcription factors can set the yeast cell on a specific differentiation pathway culminating in a particular cell type. From the DNA microarray experiments we know one effect of these key players: the activation or repression of many dozens of genes that control cell characteristics.

MCM1 was the first member of the *MADS family* of transcription factors to be discovered. (*MADS* is an acronym for the initial four factors identified in this family.) The DNA-binding proteins composing this family dimerize and contain a similar N-terminal *MADS* domain. In Section 21.3 we will encounter other *MADS* transcription factors that participate in development of skeletal muscle. *MADS* transcription factors also specify cell types in floral organs (see Figure 22-36). Acting alone, *MCM1* activates transcription of *a*-specific genes in *a* cells and of haploid-specific genes in both α and *a* cells (see Figure 21-17a, b). In haploid α cells,

◀ **FIGURE 21-18 Activity of MCM1 in a and α yeast cells.** MCM1 binds as a dimer to the P site in α -specific and **a**-specific upstream regulatory sequences (URSs), which control transcription of α -specific genes and **a**-specific genes, respectively. (a) In **a** cells, MCM1 stimulates transcription of **a**-specific genes. MCM1 does not bind efficiently to the P site in α -specific URSs in the absence of $\alpha 1$ protein. (b) In α cells, the activity of MCM1 is modified by its association with $\alpha 1$ or $\alpha 2$. The $\alpha 1$ -MCM1 complex stimulates transcription of α -specific genes, whereas the $\alpha 2$ -MCM1 complex blocks transcription of **a**-specific genes. The $\alpha 2$ -MCM1 complex also is produced in diploid cells, where it has the same blocking effect on transcription of **a**-specific genes (see Figure 21-17c).

however, the activity of MCM1 also is determined by its association with the $\alpha 1$ or $\alpha 2$ transcription factor. As a result of this combinatorial action, MCM1 promotes transcription of α -specific genes and represses transcription of **a**-specific genes in α cells. Now let's take a closer look at how MCM1 and the *MAT*-encoded proteins exert their effects.

MCM1 and $\alpha 1$ -MCM1 Complexes Activate Gene Transcription

In **a** cells, homodimeric MCM1 binds to the so-called P box sequence in the upstream regulatory sequences (URSs) of **a**-specific genes, stimulating their transcription (Figure 21-18a). Transcription of α -specific genes is controlled by two adjacent sequences—the P box and the Q box—located in the URSs associated with these genes. Although MCM1 alone binds to the P box in **a**-specific URSs, it does not bind to the P box in α -specific URSs. Thus **a** cells do not transcribe α -specific genes.

In α cells, which produce the $\alpha 1$ transcription factor encoded by *MAT α* , the simultaneous binding of MCM1 and $\alpha 1$ to PQ sites occurs with high affinity (Figure 21-18b). This binding turns on transcription of α -specific genes. Therefore, **a**-specific transcription is a simple matter of a single transcription factor binding to its target genes, while α -specific transcription requires a combination of two factors—neither of which can activate target genes alone.

$\alpha 2$ -MCM1 and $\alpha 2$ - $\alpha 1$ Complexes Repress Transcription

Highly specific binding occurs as a consequence of the interaction of $\alpha 2$ with other transcription factors at different sites in DNA. Flanking the P box in each **a**-specific URS are two $\alpha 2$ -binding sites. Both MCM1 and $\alpha 2$ can bind independently to an **a**-specific URS with relatively low affinity. In α cells, however, highly cooperative, simultaneous binding of both $\alpha 2$ and MCM1 proteins to these sites occurs with high affinity. This high-affinity binding represses transcription of

a-specific genes, ensuring that they are not expressed in α cells and diploid cells (see Figure 21-18b, right). MCM1 promotes binding of $\alpha 2$ to an **a**-specific URS by orienting the two DNA-binding domains of the $\alpha 2$ dimer to the $\alpha 2$ -binding sequences in this URS. Since a dimeric $\alpha 2$ molecule binds to both sites in an α -specific URS, each DNA site is referred to as a half-site. The relative positions of both half-sites and their orientation are highly conserved among different **a**-specific URSs.

Combinations of transcription factors create additional specificity in gene regulation. The presence of numerous $\alpha 2$ -binding sites in the genome and the “relaxed” specificity of $\alpha 2$ protein may expand the range of genes that it can regulate. For instance, in **a**/ α diploid cells, $\alpha 2$ forms a heterodimer with $\alpha 1$ that represses both haploid-specific genes and the gene encoding $\alpha 1$ (see Figure 21-17c). The example of $\alpha 2$ suggests that relaxed specificity may be a general strategy for increasing the regulatory range of a single transcription factor.

Pheromones Induce Mating of α and **a** Cells to Generate a Third Cell Type

An important feature of the yeast life cycle is the ability of haploid **a** and α cells to mate, that is, attach and fuse giving rise to a diploid **a**/ α cell (see Figure 1-6). Each haploid cell type secretes a different *mating factor*, a small polypeptide **pheromone**, and expresses a cell-surface G protein-coupled receptor that recognizes the pheromone secreted by cells of the other type. Thus **a** and α cells both secrete and respond to pheromones (Figure 21-19). Binding of the mating factors to their receptors induces expression of a set of genes encoding proteins that direct arrest of the cell cycle in G₁ and promote attachment/fusion of haploid cells to form diploid cells. In the presence of sufficient nutrients, the diploid cells will continue to grow. Starvation, however, induces diploid cells to progress through meiosis, each yielding four haploid spores. If the environmental conditions become conducive to vegetative growth, the spores will germinate and undergo mitotic division.

▲ FIGURE 21-19 Pheromone-induced mating of haploid yeast cells. The α cells produce α mating factor and a -factor receptor; the a cells produce a factor and α -factor receptor. Binding of the mating factors to their cognate receptors on cells of the opposite type leads to gene activation, resulting in mating and production of diploid cells. In the presence of sufficient nutrients, these cells will grow as diploids. Without sufficient nutrients, cells will undergo meiosis and form four haploid spores.

Studies with yeast mutants have provided insights into how the a and α pheromones induce mating. For instance, haploid yeast cells carrying mutations in the *sterile 12* (*STE12*) locus cannot respond to pheromones and do not

mate. The *STE12* gene encodes a transcription factor that binds to a DNA sequence referred to as the pheromone-responsive element, which is present in many different a - and α -specific URSs. Binding of mating factors to cell-surface receptors induces a cascade of signaling events, resulting in phosphorylation of various proteins including the Ste12 protein (see Figure 16-28a). This rapid phosphorylation is correlated with an increase in the ability of Ste12 to stimulate transcription. It is not yet known, however, whether Ste12 must be phosphorylated to stimulate transcription in response to pheromone.

Interaction of Ste12 protein with DNA has been studied most extensively at the URS controlling transcription of *STE2*, an a -specific gene encoding the receptor for the α pheromone. Pheromone-induced production of the α receptor encoded by *STE2* increases the efficiency of the mating process. Adjacent to the a -specific URS in the *STE2* gene is a pheromone-responsive element that binds Ste12. When a cell is treated with α pheromone, transcription of the *STE2* gene increases in a process that requires Ste12 protein. Ste12 protein has been found to bind most efficiently to the pheromone-responsive element in the *STE2* URS when MCM1 is simultaneously bound to the adjacent P site. We saw previously that MCM1 can act as an activator or a repressor at different URSs depending on whether it complexes with $\alpha 1$ or $\alpha 2$. In this case, the function of MCM1 as an activator is stimulated by the binding of yet another transcription factor, Ste12, whose activity is modified by extracellular signals.

KEY CONCEPTS OF SECTION 21.2

Cell-Type Specification in Yeast

- Specification of each of the three yeast cell types—the a and α haploid cells and the diploid a/α cells—is determined by a unique set of transcription factors acting in different combinations at specific regulatory sites in the yeast genome (see Figure 21-17).
- Some transcription factors can act as repressors or activators depending on the specific regulatory sites they bind and the presence or absence of other transcription factors bound to neighboring sites.
- Binding of mating-type pheromones by haploid yeast cells activates expression of genes encoding proteins that mediate mating, thereby generating the third yeast cell type (see Figure 21-19).

21.3 Specification and Differentiation of Muscle

An impressive array of molecular strategies, some analogous to those found in yeast cell-type specification, have evolved to carry out the complex developmental pathways that characterize multicellular organisms. Muscle cells have been the focus of many such studies because their development can be studied in cultured cells as well as in intact animals. Early

advances in understanding the formation of muscle cells (myogenesis) came from discovering regulatory genes that could convert cultured cells into muscle cells. Then mouse mutations affecting those genes were created and studied to learn the functions of the proteins encoded by these genes, following which scientists have investigated how the muscle regulatory genes control other genes.

Recent microarray studies have looked for genes whose transcription differs in various subtypes of muscle in mice. These studies have identified 49 genes out of the 3000 genes examined that are transcribed at substantially different levels in red (endurance) muscle and white (fast response) muscle. Clues to the molecular basis of the functional differences between red and white muscle are likely to come from studying those 49 genes and their products.

Here we examine the role of certain transcription factors in creating skeletal muscle in vertebrates. These muscle regulators illustrate how coordinated transcription of sets of target genes can produce differentiated cell types and how a cascade of transcriptional events and signals is necessary to coordinate cell behaviors and functions.

Embryonic Somites Give Rise to Myoblasts

Vertebrate skeletal myogenesis proceeds through three stages: **determination** of the precursor muscle cells, called *myoblasts*, which commits them to a muscle cell fate; proliferation and in some cases migration of myoblasts; and their terminal differentiation into mature muscle (Figure 21-20). In the first stage, myoblasts arise from blocks of mesoderm cells, called *somites*, that are located next to the neural tube in the embryo. Specific signals from surrounding tissue play an important role in determining where myoblasts will form in the developing somite. At the molecular level, the “decision” of a mesoderm cell to adopt a muscle cell fate reflects the activation of genes encoding particular transcription factors.

As myoblasts proliferate and migrate, say, to a developing limb bud, they become aligned, stop dividing, and fuse to form a **syncytium** (a cell containing many nuclei but sharing a common cytoplasm). We refer to this multinucleate cell as a *myotube*. Concomitant with cell fusion is a dramatic rise in the expression of genes necessary for further muscle development and function.

The specific extracellular signals that induce determination of each group of myoblasts are expressed only transiently. These signals trigger production of intracellular factors that maintain the myogenic program after the inducing signals are gone. We discuss the identification and functions of these myogenic proteins, and their interactions, in the next several sections.

Myogenic Genes Were First Identified in Studies with Cultured Fibroblasts

Myogenic genes are a fine example of how transcription factors control the progressive differentiation that occurs in a

▲ **FIGURE 21-20 Three stages in development of vertebrate skeletal muscle.** Somites are epithelial spheres of embryonic mesoderm cells, some of which (the myotome) become determined as myoblasts after receiving signals from other tissues (1). After the myoblasts proliferate and migrate to the limb buds and elsewhere (2), they undergo terminal differentiation into multinucleate skeletal muscle cells, called myotubes (3). Key transcription factors that help drive the myogenic program are highlighted in yellow. See also Figure 21-23.

cell lineage. In vitro studies with the fibroblast cell line designated C3H 10T $\frac{1}{2}$ have played a central role in dissecting the transcription control mechanisms regulating skeletal myogenesis. When incubated in the presence of 5-azacytidine (a cytidine derivative that cannot be methylated), C3H 10T $\frac{1}{2}$ cells differentiate into myotubes. Upon entry into cells, 5-azacytidine is converted to 5-azadeoxycytidine triphosphate and then is incorporated into DNA in place of deoxycytidine. Because methylated deoxycytidine residues commonly are present in transcriptionally inactive DNA regions, replacement of cytidine residues with a derivative that cannot be methylated may permit activation of genes previously repressed by methylation.

The high frequency at which azacytidine-treated C3H 10T $\frac{1}{2}$ cells are converted into myotubes suggested to early workers that reactivation of one or a small number of closely linked genes is sufficient to drive a myogenic program. To test this hypothesis, researchers isolated DNA from C3H 10T $\frac{1}{2}$ cells grown in the presence of 5-azacytidine and transfected it into untreated cells. The observation that 1 in 10⁴ cells transfected with this DNA was converted into a myotube is consistent with the hypothesis that one or a small set of closely linked genes is responsible for converting fibroblasts into myotubes.

Subsequent studies led to the isolation and characterization of four different but related genes that can convert

► **EXPERIMENTAL FIGURE 21-21 Myogenic genes isolated from azacytidine-treated cells can drive myogenesis when transfected into other cells.**

(a) When C3H 10T^{1/2} cells (a fibroblast cell line) are treated with azacytidine, they develop into myotubes at high frequency. To isolate the genes responsible for converting azacytidine-treated cells into myotubes, all the mRNAs from treated cells first were isolated from cell extracts on an oligo-dT column. Because of their poly(A) tails, mRNAs are selectively retained on this column. The red mRNAs represent molecules enriched in azacytidine-treated cells; the pink ones are all other mRNAs. Steps 1 and 2: The isolated mRNAs were converted to radiolabeled cDNAs. Step 3: When the cDNAs were mixed with mRNAs from untreated C3H 10T^{1/2} cells, only cDNAs derived from mRNAs (light red) produced by both azacytidine-treated cells and untreated cells hybridized. The resulting double-stranded DNA was separated from the unhybridized cDNAs (dark blue) produced only by azacytidine-treated cells. Step 4: The cDNAs specific for azacytidine-treated cells then were used as probes to screen a cDNA library from azacytidine-treated cells (see Figure 5-16). At least some of the clones identified with these probes correspond to genes required for myogenesis. (b) Each of the cDNA clones identified in part (a) was incorporated into a plasmid carrying a strong promoter. Steps 1 and 2: C3H 10T^{1/2} cells were cotransfected with each recombinant plasmid plus a second plasmid carrying a gene conferring resistance to an antibiotic called G418; only cells that have incorporated the plasmids will grow on a medium containing G418. One of the selected clones, designated *myoD*, was shown to drive conversion of C3H 10T^{1/2} cells into muscle cells, identified by their binding of labeled antibodies against myosin, a muscle-specific protein (step 3). [See R. L. Davis et al., 1987, *Cell* 51:987.]

C3H 10T^{1/2} cells into muscle. Figure 21-21 outlines the experimental protocol for identifying and assaying one of these genes, called the *myogenic determination (myoD)* gene. C3H 10T^{1/2} cells transfected with *myoD* cDNA and those treated with 5-azacytidine both formed myotubes. The *myoD* cDNA also was able to convert a number of other cultured cell lines into muscle. Based on these findings, the *myoD* gene was proposed to play a key role in muscle development. A similar approach identified three other genes—*myogenin*, *myf5*, and *mrf4*—that also function in muscle development.

Two Classes of Regulatory Factors Act in Concert to Guide Production of Muscle Cells

The four myogenic proteins—MyoD, Myf5, myogenin, and MRF4—are all members of the **basic helix-loop-helix (bHLH)** family of DNA-binding transcription factors (see Figure 7-26). Near the center of these proteins is a basic DNA-binding (B) region adjacent to the HLH domain, which mediates dimer formation. Flanking this central DNA-binding/dimerization region are two activation domains. We refer to the four myogenic bHLH proteins collectively as *muscle regulatory factors*, or *MRFs* (Figure 21-22a).

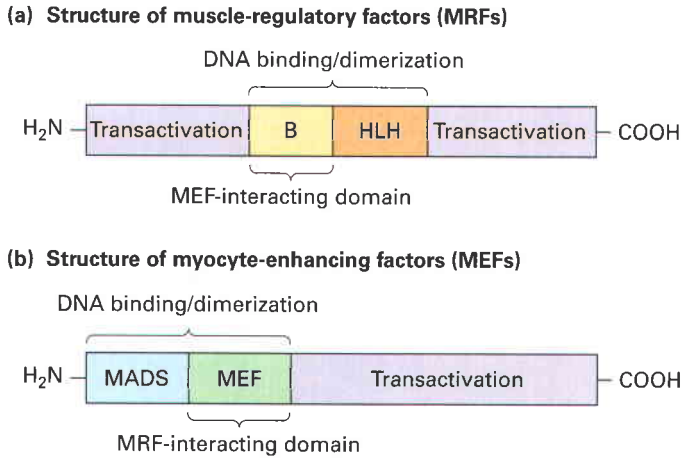

bHLH proteins form homo- and heterodimers that bind to a 6-bp DNA site with the consensus sequence CANNTG (N = any nucleotide). Referred to as the E box, this sequence is present in many different locations within the genome (on a purely random basis the E box will be found every 256 nucleotides). Thus some mechanism(s) must ensure that MRFs

(a) Screen for myogenic genes

(b) Assay for myogenic activity of *myoD* cDNA

▲ FIGURE 21-22 General structures of two classes of transcription factors that participate in myogenesis. MRFs (muscle regulatory factors), such as myogenin and MyoD, are bHLH (basic helix-loop-helix) proteins produced only in developing muscle. MEFs (myocyte-enhancing factors), which are produced in several tissues in addition to developing muscle, belong to the MADS family. The myogenic activity of MRFs is enhanced by their interaction with MEFs. The domain structures of the proteins are shown, including transactivation, basic (B), helix-loop-helix (HLH), MADS and MEF domains.

specifically regulate muscle-specific genes and not other genes containing E boxes in their transcription-control regions. One clue to how this myogenic specificity is achieved was the finding that the DNA-binding affinity of MyoD is tenfold greater when it binds as a heterodimer complexed with E2A, another bHLH protein, than when it binds as a homodimer. Moreover, in azacytidine-treated C3H 10T $\frac{1}{2}$ cells, MyoD is found as a heterodimer complexed with E2A, and both proteins are required for myogenesis in these cells. The DNA-binding domains of E2A and MyoD have similar but not identical amino acid sequences, and both proteins recognize E box sequences. The other MRFs also form heterodimers with E2A that have properties similar to MyoD–E2A complexes. This heterodimerization restricts activity of the myogenic transcription factors to genes that contain at least two E boxes located close to each other.

Since E2A is expressed in many tissues, the requirement for E2A is not sufficient to confer myogenic specificity. Subsequent studies suggested that specific amino acids in the bHLH domain of all the MRFs confer myogenic specificity by allowing MRF–E2A complexes to bind specifically to another family of DNA-binding proteins called *myocyte enhancing factors*, or *MEFs*. MEFs were considered excellent candidates for interaction with MRFs for two reasons. First, many muscle-specific genes contain recognition sites for both MEFs and MRFs. Second, although MEFs cannot induce myogenic conversion of azacytidine-treated C3H 10T $\frac{1}{2}$ cells by themselves, they enhance the ability of MRFs to do so. This enhancement requires physical interaction between a MEF and MRF–E2A heterodimer. MEFs belong to the MADS family of transcription factors and contain a MEF domain, adjacent to the MADS domain, that mediates interac-

tion with myogenin (Figure 21-22b). The synergistic action of the MEF homodimer and MRF–E2A heterodimer is thought to drive high-level expression of muscle-specific genes.

Knockout mice and *Drosophila* mutants have been used to explore the roles of MRF and MEF proteins in conferring myogenic specificity in intact animals, extending the work in cell culture. These experiments demonstrated the importance of three of the MRF proteins (MyoD, Myf5, and myogenin) and of MEF proteins for distinct steps in muscle development (see Figure 21-20). The function of the fourth myogenic protein, Mrf4, is not entirely clear.

Differentiation of Myoblasts Is Under Positive and Negative Control

Powerful developmental regulators like the MRFs cannot be allowed to run rampant. In fact, their actions are circumscribed at several levels. First, production of the muscle regulators is activated only in mesoderm cells in response to locally acting signals, such as Hedgehog, Wnt, and BMP, that are produced at the right time and place in the embryo. Other proteins mediate additional mechanisms for assuring tight control over myogenesis: chromatin-remodeling proteins are needed to make target genes accessible to MRFs; inhibitory proteins can restrict when MRFs act; and antagonistic relations between cell-cycle regulators and differentiation factors like MRFs ensure that differentiating cells will not divide, and vice versa. All these factors control when and where muscles form.

Activating Chromatin-Remodeling Proteins MRF proteins control batteries of muscle-specific genes, but can do so only if chromatin factors allow access. Remodeling of chromatin, which usually is necessary for gene activation, is carried out by large protein complexes (e.g., SWI/SNF complex) that have ATPase and perhaps helicase activity. These complexes recruit histone acetylases that modify chromatin to make genes accessible to transcription factors (Chapter 7). The hypothesis that remodeling complexes help myogenic factors was tested using dominant-negative versions of the ATPase proteins that form the cores of these complexes. (Recall from Chapter 5 that a dominant-negative mutation produces a mutant phenotype even when a normal allele of the gene also is present.) When genes carrying these dominant-negative mutations were transfected into C3H 10T $\frac{1}{2}$ cells, the subsequent introduction of myogenic genes no longer converted the cells into myotubes. In addition, a muscle-specific gene that is normally activated did not exhibit its usual pattern of chromatin changes in the doubly transfected C3H 10T $\frac{1}{2}$ cells. These results indicate that transcription activation by myogenic proteins depends on a suitable chromatin structure in the regions of muscle-specific genes. MEF2 recruits histone acetylases such as p300/CBP, through another protein that serves as a mediator, thus activating transcription of target genes. Chromatin immunoprecipitation experiments with antibodies against acetylated histone H4 show that the acetylated histone level associated with MEF2-regulated genes is higher in differentiated myotubes than in myoblasts (see Figure 7-37).

Inhibitory Proteins Screening for genes related to *myoD* led to identification of a related protein that retains the HLH dimerization region but lacks the basic DNA-binding region and hence is unable to bind to E box sequences in DNA. By binding to MyoD or E2A, this protein inhibits formation of MyoD–E2A heterodimers and hence their high-affinity binding to DNA. Accordingly, this protein is referred to as Id, for inhibitor of DNA binding. Id prevents cells that produce MyoD and E2A from activating transcription of the muscle-specific gene encoding creatine kinase. As a result, the cells remain in a proliferative growth state. When these cells are induced to differentiate into muscle (for instance, by the removal of serum, which contains the growth factors required for proliferative growth), the Id concentration falls. MyoD–E2A dimers now can form and bind to the regulatory regions of target genes, driving differentiation of C3H 10T $\frac{1}{2}$ cells into myoblast-like cells.

The role of histone deacetylases, which inhibit transcription, in muscle development was revealed in experiments in which scientists first introduced extra *myoD* genes into cultured C3H 10T $\frac{1}{2}$ cells to raise the level of MyoD. This resulted in increased activation of target genes and more rapid differentiation of the cells into myotubes. However, when genes encoding histone deacetylases also were introduced into the C3H 10T $\frac{1}{2}$ cells, the muscle-inducing effect of MyoD was blocked and the cells did not differentiate into myotubes. The explanation for how histone deacetylases inhibit MyoD-induced muscle differentiation came from the surprising finding that the muscle gene activator MEF2 can bind, through its MADS domain, to a histone deacetylase. This interaction, which can prevent MEF2 function and muscle differentiation, is normally blocked during differentiation because the histone deacetylase is phosphorylated by a Ca²⁺/calmodulin-dependent protein kinase; the phosphorylated deacetylase then is moved from the nucleus to the cytoplasm. Taken together, these results indicate that activation of muscle genes by MyoD and MEF2 is in competition with inactivation of muscle genes by repressive chromatin structures.

Cell-Cycle Proteins The onset of terminal differentiation in many cell types is associated with arrest of the cell cycle, most commonly in G₁, suggesting that the transition from the determined to differentiated state may be influenced by cell-cycle proteins including cyclins and cyclin-dependent kinases (Chapter 20). For instance, certain inhibitors of cyclin-dependent kinases can induce muscle differentiation in cell culture, and the amounts of these inhibitors are markedly higher in differentiating muscle cells than in non-differentiating ones in vivo. Conversely, differentiation of cultured myoblasts can be inhibited by transfecting the cells with DNA encoding cyclin D1 under the control of a constitutively active promoter. Expression of cyclin D1, which normally occurs only during G₁, is induced by mitogenic factors in many cell types and drives the cell cycle (see Figure 20-32). The ability of cyclin D1 to prevent myoblast differentiation in vitro may mimic aspects of the in vivo signals that antagonize the differentiation pathway. The antagonism between negative and positive regulators

of G₁ progression is likely to play an important role in controlling myogenesis in vivo.

Cell–Cell Signals Are Crucial for Determination and Migration of Myoblasts

As noted already, after myoblasts arise from somites, they must move to their proper locations and form the correct attachments as they differentiate into muscle cells (Figure 21-23). Expression of myogenic genes often occurs after elaborate events that tell certain somite cells to delaminate from the somite epithelium and guide their subsequent movements to muscle assembly sites.

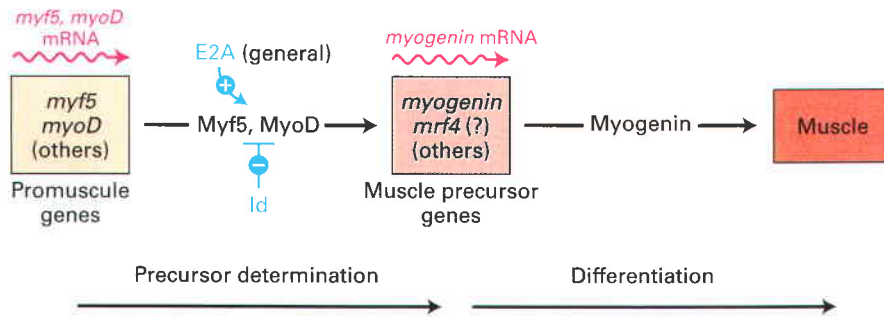

A transcription factor, Pax3, is produced in the subset of somite cells that will form muscle. Pax3 appears to be at the top of the regulatory hierarchy controlling muscle formation in the body wall and limbs. Myoblasts that will migrate, but not cells that remain behind, also produce a transcription factor called Lbx1. If Pax3 is not functional, Lbx1 transcripts are not produced and myoblasts do not migrate. Both Pax3 and Lbx1 can affect expression of *myoD*. The departure of myoblasts from somites also depends upon reception of a secreted protein signal appropriately called *scatter factor*, or *hepatocyte growth factor (SF/HGF)*. This signal, which is produced by embryonic connective tissue cells (mesenchyme) in the limb buds, attracts migrating myoblasts, thus directing them to their proper destination.

Production of SF/HGF is previously induced by still other secreted signals. If the SF/HGF signal or its receptor on myoblasts is not functional, somite cells will produce Lbx1 but not go on to migrate; thus no muscles will form in the limbs. Expression of the *myogenin* and *mrf4* genes does not begin until migrating myoblasts approach their limb-bud destinations (see Figure 21-20).

▲ **FIGURE 21-23 Embryonic determination and migration of myoblasts in mammals.** After formation of the neural tube, each somite forms sclerotome, which develops into skeletal structures, and dermamyotome, which gives rise to the dermis of the skin and to the muscles. Lateral myoblasts migrate from the dermamyotome to the limb bud; medial myoblasts develop into the trunk muscles. The remainder of a dermamyotome gives rise to the connective tissue of the skin. [Adapted from M. Buckingham, 1992, *Trends Genet.* 8:144.]

Vertebrate myogenesis

Fly neurogenesis

We have touched on just a few of the many external signals and transcription factors that participate in development of a properly patterned muscle. The function of all these regulatory molecules must be coordinated both in space and in time during myogenesis.

bHLH Regulatory Proteins Function in Creation of Other Tissues

Four bHLH transcription factors that are remarkably similar to the myogenic bHLH proteins control neurogenesis in *Drosophila*. Similar proteins appear to function in neurogenesis in vertebrates and perhaps in the determination and differentiation of hematopoietic cells.

The neurogenic *Drosophila* bHLH proteins are encoded by an ~100-kb stretch of genomic DNA, termed the *achaete-scute complex* (AS-C), containing four genes designated *achaete* (*ac*), *scute* (*sc*), *lethal of scute* (*l'sc*), and *asense* (*a*). Analysis of the effects of loss-of-function mutations indicate that the Achaete (Ac) and Scute (Sc) proteins participate in determination of neuronal stem cells, called neuroblasts in flies, while the Asense (As) protein is required for differentiation of the progeny of these cells into neurons. (Note that the term *neuroblasts* refers to stem cells in flies but to precursor cells in mammals.) These functions are analogous to the roles of MyoD and Myf5 in muscle determination and of myogenin in differentiation. Two other *Drosophila* proteins, designated Da and Emc, are analogous in structure and function to vertebrate E2A and Id, respectively. For example, heterodimeric complexes of Da with Ac or Sc bind to DNA better than the homodimeric forms of Ac and Sc. Emc, like Id, lacks any DNA-binding domain; it binds to Ac and Sc proteins, thus inhibiting their association with Da and binding to DNA. The similar functions of these myogenic and neurogenic proteins are depicted in Figure 21-24.

◀ **FIGURE 21-24 Comparison of genes that regulate vertebrate myogenesis and fly neurogenesis.** bHLH transcription factors have analogous functions in determination of neural and muscle precursor cells and their subsequent differentiation into mature neurons and muscle cells. In both cases, the proteins encoded by the earliest-acting genes (*left*) are under both positive and negative control by other related proteins (blue type). See text for details. [Adapted from Y. N. Jan and L. Y. Jan, 1993, *Cell* 75:827.]

A family of bHLH proteins related to the *Drosophila* Achaete and Scute proteins has been identified in vertebrates. One of these, called neurogenin, controls the formation of neuroblasts. In situ hybridization experiments showed that neurogenin is produced at an early stage in the developing nervous system and induces production of NeuroD, another bHLH protein that acts later (Figure 21-25a). Injection of large amounts of *neurogenin* mRNA into *Xenopus* embryos further demonstrated the ability of neurogenin to induce neurogenesis (Figure 21-25b). The function of neurogenin is analogous to that of the Achaete and Scute in *Drosophila*; likewise, NeuroD and Asense may have analogous functions in vertebrates and *Drosophila*.

KEY CONCEPTS OF SECTION 21.3

Specification and Differentiation of Muscle

- Development of skeletal muscle begins with the signal-induced determination of certain mesoderm cells in somites as myoblasts. Following their proliferation and migration, myoblasts stop dividing and differentiate into multinucleate muscle cells (myotubes) that express muscle-specific proteins (see Figure 21-20).
- Four myogenic bHLH transcription factors—MyoD, myogenin, Myf5, and MRF4, collectively called muscle-regulatory factors (MRFs)—associate with E2A and MEFs to form large transcriptional complexes that drive myogenesis and expression of muscle-specific genes.
- Dimerization of bHLH transcription factors with different partners modulates the specificity or affinity of their binding to specific DNA regulatory sites, and also may prevent their binding entirely.
- The myogenic program driven by MRFs depends on the SWI/SNF chromatin-remodeling complex, which makes target genes accessible.

▲ EXPERIMENTAL FIGURE 21-25 In situ hybridization and injection experiments demonstrate that neurogenin acts before NeuroD in vertebrate neurogenesis. (a) Sections of rat neural tube were treated with a probe specific for *neurogenin* mRNA (left) or *neuroD* mRNA (right). The open space in the center is the ventricle, and the cells lining this cavity constitute the subventricular layer. All the neural cells are born in the subventricular layer and then migrate outward (see Figure 21-12). As illustrated in these micrographs, *neurogenin* mRNA is produced in proliferating neuroblasts in the subventricular layer (arrow), whereas *neuroD*

mRNA is present in migrating neuroblasts that have left the ventricular zone (arrow). (b) One of the two cells in early *Xenopus* embryos was injected with *neurogenin* mRNA (inj) and then stained with a probe specific for neuron-specific mRNAs encoding β -tubulin (left) or NeuroD (right). The region of the embryo derived from the uninjected cell served as a control (con). The *neurogenin* mRNA induced a massive increase in the number of neuroblasts expressing *neuroD* mRNA and neurons expressing β -tubulin mRNA in the region of the neural tube derived from the injected cell. [From Q. Ma et al., 1996, *Cell* **87**:43; courtesy of D. J. Anderson.]

- The myogenic program is inhibited by binding of Id protein to MyoD, which blocks binding of MyoD to DNA, and by histone deacetylases, which repress activation of target genes by MRFs.
- Migration of myoblasts to the limb buds is induced by scatter factor/hepatocyte growth factor (SF/HGF), a protein signal secreted by mesenchymal cells (see Figure 21-23). Myoblasts must express both the Pax3 and Lbx1 transcription factors to migrate.
- Terminal differentiation of myoblasts and induction of muscle-specific proteins do not occur until myoblasts stop dividing and migrating.
- Neurogenesis in *Drosophila* depends upon a set of four neurogenic bHLH proteins that are conceptually and structurally similar to the vertebrate myogenic proteins (see Figure 21-24).
- A related vertebrate protein, neurogenin, is required for formation of neural precursors and also determines their fate as neurons or glial cells.

21.4 Regulation of Asymmetric Cell Division

During embryogenesis, the earliest stage in animal development, asymmetric cell division often creates the initial diversity that ultimately culminates in formation of specific differentiated cell types. Both stem cells and precursor cells can divide asymmetrically via similar mechanisms, although the details vary with the tissue. Even in bacteria, cell division

may yield unequal daughter cells, for example, one that remains attached to a stalk and one that develops flagella used for swimming.

Essential to asymmetric cell division is *polarization* of the parental cell and then differential incorporation of parts of the parental cell into the two daughters (Figure 21-26). A variety of molecular mechanisms are employed to create and propagate the initial asymmetry that polarizes the parental cell. In addition to being different, the daughter cells must often be placed in a specific orientation with respect to surrounding structures. When stem cells divide asymmetrically, the cell that remains in contact with niche signals will persist as a stem cell. Therefore, the mitotic spindles and cell polarity must be aligned with the overall tissue so that differentiating cells move off in the right direction, and so that at least one daughter remains in the stem-cell niche to perpetuate the stem-cell population. This phenomenon is exemplified in the division of neural stem cells during embryonic development (see Figure 21-12b).

We begin with an especially well-understood example of asymmetric cell division, the budding of yeast cells, and move on to recently discovered protein complexes important for asymmetric cell divisions in multicellular organisms. We see in the yeast example an elegant system that links asymmetric division to the process of controlling cell type.

Yeast Mating-Type Switching Depends upon Asymmetric Cell Division

S. cerevisiae cells use a remarkable mechanism to control the differentiation of the cells as the cell lineage progresses. Whether a haploid yeast cell exhibits the α or a mating type

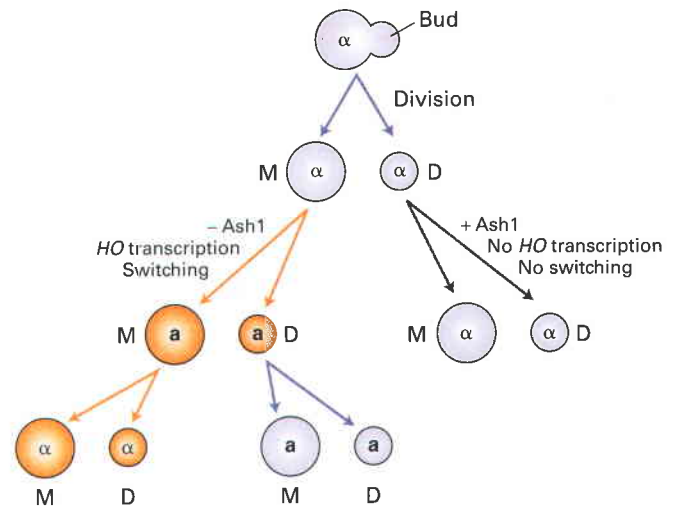

▲ **FIGURE 21-26 General features of asymmetric cell division.**

Various mechanisms can lead to asymmetric distribution of cytoplasmic components, such as particular proteins or mRNAs (red dots), thereby forming a polarized parental cell. Division of a polarized cell will be asymmetric if the mitotic spindle is oriented so that the localized cytoplasmic components are distributed unequally to the two daughter cells, as shown here. However, if the spindle is positioned differently relative to the localized cytoplasmic components, division of a polarized cell may produce equivalent daughter cells.

is determined by which genes are present at the *MAT* locus (see Figure 21-17). As described in Chapter 7, the *MAT* locus in the *S. cerevisiae* genome is flanked by two “silent,” transcriptionally inactive loci containing the alternative α or *a* sequences (see Figure 7-33). A specific DNA rearrangement brings the genes that encode the α -specific or *a*-specific transcription factors from these silent loci to the active *MAT* locus where they can be transcribed.

Interestingly, some haploid yeast cells can switch repeatedly between the α and *a* types. *Mating-type switching* occurs when the α allele occupying the *MAT* locus is replaced by the *a* allele, or vice versa. The first step in this process is catalyzed by *HO* endonuclease, which is expressed in mother cells but not in daughter cells. Thus mating-type switching occurs only in mother cells (Figure 21-27). Transcription of the *HO* gene is dependent on the SWI/SNF chromatin-remodeling complex (see Figure 7-43), the same complex that we encountered earlier in our discussion of myogenesis. Daughter yeast cells arising by budding from mother cells contain a protein called Ash1p (for Asymmetric synthesis of *HO*) that prevents recruitment of the SWI/SNF complex to the *HO* gene, thereby preventing its transcription. The absence of Ash1 from mother cells allows them to transcribe the *HO* gene.

Recent experiments have revealed how the asymmetry in the distribution of Ash1 between mother and daughter cells is established. *ASH1* mRNA accumulates in the growing bud that will form a daughter cell due to the action of a myosin motor protein (Chapter 17). This motor protein, called

▲ **FIGURE 21-27 Switching of mating type in haploid yeast cells.** Division by budding forms a larger mother cell (M) and smaller daughter cell (D), both of which have the same mating type as the original cell (α in this example). The mother cell can switch mating type during G_1 of the next cell cycle and then divide again, producing two cells of the opposite *a* type. Switching depends on transcription of the *HO* gene, which occurs only in the absence of Ash1 protein. The smaller daughter cells, which produce Ash1 protein, cannot switch; after growing in size through interphase, they divide to form a mother cell and daughter cell. Orange cells and arrows indicate switch events.

Myo4p, moves the *ASH1* mRNA, as a ribonucleoprotein complex, along actin filaments in one direction only, toward the bud (Figure 21-28). Two connector proteins, termed She2p and She3p (for SWI5p-dependent *HO* expression) tether the *ASH1* mRNA to the *Myo4p* motor protein. By the time the bud separates from the mother cell, the mother cell is largely depleted of *ASH1* mRNA and thus can switch mating type in the following G_1 before additional *ASH1* mRNA is produced and before DNA replication in the S phase.

Budding yeasts use a relatively simple mechanism to create molecular differences between the two cells formed by division. In higher organisms, as in yeast, the mitotic spindle must be oriented in such a way that each daughter cell receives its own set of cytoplasmic components. Genetic studies in *C. elegans* and *Drosophila* have revealed the key participants, a first step in understanding at the molecular level how asymmetric cell division is regulated in multicellular organisms. To illustrate these complexities, we focus on asymmetric division of neuroblasts in *Drosophila*.

Proteins That Regulate Asymmetry Are Localized at Opposite Ends of Dividing Neuroblasts in *Drosophila*

Fly neuroblasts, which are stem cells, arise from a sheet of ectoderm cells that is one cell thick. As in vertebrates, the *Drosophila* ectoderm forms both epidermis and the nervous system, and many ectoderm cells have the potential to

► **FIGURE 21-28 Model for restriction of mating-type switching to mother cells in *S. cerevisiae*.** Ash1 protein prevents a cell from transcribing the *HO* gene whose encoded protein initiates the DNA rearrangement that results in mating-type switching from **a** to α or α to **a**. Switching occurs only in the mother cell, after it separates from a newly budded daughter cell, because of the presence of Ash1 protein only in the daughter cell. The molecular basis for this differential localization of Ash1 is the one-way transport of *ASH1* mRNA into the bud. A linking protein, She2p, binds to specific 3' untranslated sequences in the *ASH1* mRNA and also binds to She3p protein. This protein in turn binds to a myosin motor, Myo4p, which moves along actin filaments into the bud. [See S. Koon and B. J. Schnapp, 2001, *Curr. Biology* 11:R166.]

assume either a neural or epidermal fate. Under the control of genes that become active only in certain cells, some of the cells increase in size and begin to loosen from the ectodermal layer. At this point, the delaminating cells use the Delta/Notch signaling pathway to mediate **lateral inhibition** of their neighbors, causing them to retain the epidermal fate (see Figures 16-36 and 22-42). The delaminating cells move inside and become spherical neuroblasts, while the prospective epidermal cells remain behind and close up to form a tight sheet. This process generates 60 neuroblasts

in each body segment, which will give rise to about 700 neurons per segment.

Once formed, the neuroblasts undergo asymmetric divisions, at each division recreating themselves and producing a *ganglion mother cell (GMC)* on the basal side of the neuroblast (Figure 21-29). A single neuroblast will produce several GMCs; each GMC in turn forms two neurons. Depending on where they form in the embryo and consequent regulatory events, neuroblasts may form more or fewer GMCs. Neuroblasts and GMCs in different locations exhibit different

► **FIGURE 21-29 Asymmetric cell division during *Drosophila* neurogenesis.** The ectodermal sheet (1) of the early embryo gives rise to both epidermal cells and neural cells. Neuroblasts, the stem cells for the fly nervous system, are formed when ectoderm cells enlarge, separate from the ectodermal epithelium, and move into the interior of the embryo (2–4). Each neuroblast that arises divides asymmetrically to recreate itself and produce a ganglion mother cell, or GMC (5). Subsequent divisions of a neuroblast produce more GMCs, creating a stack of these precursor cells (6). Each GMC divides once to give rise to two neurons (7). Neuroblasts and their neuronal descendants can have different fates depending on their location. The micrograph shows an asymmetrically dividing *Drosophila* neuroblast. The apical end (red) will form a new neuroblast and the basal end (blue and red) will form a GMC. The microtubules are labeled in green. [Photograph courtesy of Dr. C. Q. Doe, University of Oregon.]

patterns of gene expression, an indicator of their fates. Analysis of fly mutants led to the discovery of key proteins that (1) establish apical-basal polarity in neuroblasts, (2) align the mitotic spindle of dividing neuroblasts with their polarity, and (3) direct formation of daughter cells whose fate and size differ from that of neuroblasts. Genetic studies of asymmetric cell divisions in the *C. elegans* early embryo independently led to the discovery of important cell division asymmetry proteins. The machinery controlling asymmetric cell division is highly conserved and readily recognized from worms to flies to mammals, indicating conservation of protein functions for more than half a billion years.

Basal and apical protein complexes congregate during each neuroblast division, disperse, and then localize again for the next round of division. Four protein complexes, which we denote as MPSB, BPP, DSL, and IPLG, govern the entire process (Figure 21-30):

- **BPP**, an apical complex also known as the PAR complex, is responsible for defining the end of the cell that will remain a neuroblast. It comprises *Bazooka* and *Par6*, both of which contain PDZ domains, and *aPKC*, an atypical isoform of protein kinase C.
- **IPLG**, a second apical complex, is composed of *Inscuteable* (*Insc*), *Partner of inscuteable* (*Pins*), *Locomotion defects* (*Loco*), and *G_i*, a heterotrimeric G protein (Chapter 15). This complex is critical for orienting the spindle during asymmetric divisions.
- **DSL**, a complex that is fairly evenly distributed around the cell, is composed of *Discs-large* (*Dlg*), *Scribble* (*Scrib*),

▲ **FIGURE 21-30 Localized protein complexes that control asymmetric cell division.** (a) In the *Drosophila* neuroblast, the BPP complex is localized apically in ectoderm cells and in delaminating neuroblasts (steps 1–3 in Figure 21-29). The IPLG complex is also apically localized. The DSL complex (not shown) is distributed fairly evenly around the cells. In response to regulation by BPP, the MPSB complex localizes to the basal side, where it will be incorporated into the ganglion mother cell (GMC). Mutations in genes that encode polarized proteins disrupt asymmetric cell division and are therefore fatal. Motor protein-mediated transport along cytoskeletal filaments localizes the MPSB basal complex. [See C. Q. Doe and B. Bowerman, 2001, *Curr. Opin. Cell Biol.* 13:68, and A. Wodarz, 2005, *Curr. Opin. Cell Biol.* 17:475.]

and *Lethal giant larvae* (*Lgl*). *Lgl* reversibly associates with the cytoskeleton. The DSL complex is mostly employed in localizing basal proteins.

- **MPSB**, a basal complex, confers GMC cell fate. It includes the coiled-coil scaffold protein *Miranda*, the homeodomain-class transcription factor *Prospero*, the RNA-binding protein *Staufen*, and a translational repressor protein called *Brain tumor* (*Brat*).

With the key players in neuroblast asymmetric division introduced, let's examine their functions more closely.

Apical Complexes and Spindle Orientation For localized protein complexes to be differentially incorporated into two daughter cells, the plane of cell division must be appropriately oriented. In dividing fly neuroblasts, the **mitotic spindle** first aligns perpendicular to the apical-basal axis and then turns 90 degrees to align with it at the same time that the basal complexes become localized to the basal side (Figure 21-31). The apical IPLG and BPP complexes, which are already in place before spindle rotation, control the final orientation of the spindle. This is supported by the finding that mutations in any of the components of these complexes eliminate the coordination of the spindle with apical-basal polarity, causing the spindle orientation to become random.

The two apical protein complexes have different roles in spindle orientation. First, the BPP complex responds to extrinsic cues from the overlying ectoderm to form an apical crescent at late interphase. In this way, the BPP complex aligns neuroblast polarity with the surrounding tissue so that the apical side of the neuroblast is always next to the ectoderm. Second, the BPP complex recruits the IPLG complex to the apical cortex, and the BPP complex anchors one spindle pole to the apical cortex, thereby aligning the spindle along the apical-basal axis. The direct link with the spindle is mediated by the NuMA protein, which joins the Pins protein of the IPLG complex to microtubules. The IPLG complex is sufficient for anchoring the spindle and promoting asymmetric division.

Basal Complex and the Determination of GMC Fate During fly neuroblast divisions, the MPSB complex becomes localized to the basal cortex prior to each division and remains there while the basal part of the neuroblast becomes a new GMC (see Figure 21-30). *Miranda* provides a scaffold for the other three proteins in the complex (*Prospero*, *Staufen*, and *Brat*) and is needed to muster them near the basal plasma membrane. After each division, MPSB proteins in the basally located daughter cell inhibit neuroblast properties and confer GMC properties. *Prospero* negatively regulates transcription of cell-cycle genes, which remain active in the dividing neuroblast. *Brat* post-transcriptionally inhibits the transcription factor *Myc*, a positive regulator of cell division and negative regulator of cell size. In this way *Brat* helps keep the GMC small and restrains its division. Genetic studies provide support for such involvement of *Prospero* and *Brat* in determination of GMCs. For example, *brat* mutations

▲ EXPERIMENTAL FIGURE 21-31 Time-lapse fluorescence imaging reveals rotation of the mitotic spindle in asymmetrically dividing neuroblasts. Early *Drosophila* embryos were injected with a hybrid gene composed of the gene encoding green fluorescent protein (GFP) fused to the gene encoding Tau, a protein that binds to microtubules. At the top are time-lapse images of a single dividing neuroblast in a live embryo. The basal side is at the top, and the apical side at the bottom. At time 0, equivalent to

prophase, the two centrosomes are visible on opposite sides of the cell. These function as the spindle poles; as mitosis proceeds, the microtubules forming the mitotic spindle are assembled from the poles (see Figure 18-34). In successive images (at 32, 64, and 80 seconds), the bipolar spindle can be seen to form and rotate 90 degrees to align with the apical-basal axis, as schematically depicted at the bottom. [From J. A. Kaltschmidt et al., 2000, *Nature Cell Biol.* **2**:7; courtesy of J. Kaltschmidt and A. H. Brand, Wellcome/CRC Institute, Cambridge University.]

cause GMCs to enlarge into neuroblasts and keep dividing, whereas loss of Prospero causes GMCs to remain small but maintain neuroblast-style gene expression and proliferation.

How does the MPSB complex become located basally prior to each neuroblast division? The answer is more complex than Ash1p localization in yeast. Both apical BPP and uniform cortical DSL complexes are involved. The BPP complex controls MPSB localization. The atypical protein kinase C (aPKC), a component of the BPP complex, phosphorylates and thus inactivates the Lgl protein, a component of the DSL complex. Lgl is required to bring MPSB proteins to the basal cortex. Since aPKC is located at the apical end of the cells, Lgl is active only in basal regions. The restriction of active Lgl to basal cortex explains how MPSB proteins are brought to the basal cortex where they cause one daughter cell to become a GMC.

How does active, basal Lgl control localization of MPSB? Although the full story is not yet known, genetic and biochemical studies show that actin, myosin II, and myosin VI are involved. For instance, drug-induced disruption of actin microfilaments blocks MPSB targeting to the neuroblast cortex. Myosin VI binds Miranda (the “M” of MPSB) directly and is also required for basal targeting of the MPSB complex.

Asymmetry of Daughter Cell Size A notable feature of neuroblast asymmetric division is the pronounced difference in the size of neuroblasts and GMCs. This cell-size difference is regulated by the Pins and $G_{\alpha i}$ components of the IPLG complex. The IPLG complex is brought to the apical cortex by virtue of the association of its Insc component with the Baz component of the BPP complex. When a neuroblast divides to produce a GMC and a neuroblast, the GMC is usually considerably smaller. The spindle is oriented, as we have described, in the apical-basal direction, and at metaphase of the neuroblast division, the two halves of the spindle are about

equal in size. However the two centrosomes, one at each pole of the spindle, behave differently. The basal centrosome, marking the pole where the GMC will form, has few astral microtubules, while the apical centrosome enlarges and grows a bushy mass of astral microtubules that make that pole of the dividing neuroblast considerably larger (Figure 21-32).

▲ FIGURE 21-32 Orientation of mitotic spindle and difference in daughter cell size in asymmetric division of neuroblasts.

Interactions between spindle microtubules and the IPLG apical complex orient the spindle. Actin microfilaments (red) lie just under the cell surface at all times. Microtubules (blue) radiate from the centrosome during interphase and then assemble into the mitotic spindle, attached to the duplicated centrosomes, during cell division. Note the biased location of the centrosome during interphase, at the apical end of the cell. The asymmetry in daughter cell size begins with differential assembly of astral microtubules, which are considerably shorter and less abundant in the basal end of the dividing cell, which forms the daughter ganglion mother cell (GMC). [Adapted from C. Q. Doe and B. Bowerman, 2001, *Curr. Opin. Cell Biol.* **13**:68.]

Genetic tests have shown redundant control of the cell-size asymmetry between the two daughter cells. If either the BPP apical complex or the IPLG apical complex is functional, the cells formed will be the usual small GMC and large neuroblast. In contrast, a double mutant with defects in both the BPP and IPLG complexes (e.g., a double *pins* and *baz* mutant) produces two daughter cells that are equal in size. Double mutations that inactivate the G_β and G_γ subunits, but not the $G_{\alpha i}$ subunit, of the G_i protein component of the IPLG complex, cause numerous astral microtubules to form on both centrosomes. Over-production of the G_β protein has the opposite effect—no astral tubules on either centrosome. From these genetic analyses we may conclude that a normal function of the G_β protein is to selectively prevent assembly of astral microtubules at the basal centrosome. This regulation would involve the action of G_β/G_γ subunits that are *not* part of the apical IPLG complexes. Indeed, G_β is uniformly distributed all around the neuroblast cortex.

Heterotrimeric G proteins like the one in the IPLG complex often are controlled by a G protein-coupled receptor that, when activated, dissociates the trimer by binding G_α and releasing active G_β/G_γ subunits (Chapter 15). No sign of a G protein-coupled receptor has been found in the search for proteins controlling neuroblast asymmetry. Instead *Pins* and *Loco*, components of the IPLG complex, substitute for a receptor in triggering dissociation of the inactive heterotrimeric G protein. *Pins* and *Loco* are partially redundant; mutating both causes defects equivalent to mutation of either the G_β or G_γ subunit. *Pins* and *Loco* bind to GDP- $G_{\alpha i}$ and act like guanine nucleotide dissociation inhibitors, thereby keeping $G_{\alpha i}$ associated with GDP and allowing $G_{\alpha i}$ -GDP and G_β/G_γ to act upon their (as yet unknown) targets. As would be expected for a typical G protein cycle, a GTPase-activating protein (GAP) and a GDP exchange factor (GEF) have also been found to regulate neuroblast division asymmetry. The GAP reaction inactivates the G protein by breaking down GTP to GDP, while the GEF reaction recharges the G protein for activity by bringing in a new GTP. The mechanism by which the G protein component of the IPLG complex regulates the activity of the centrosome remains unknown.

Summary of Asymmetry-Determining Protein Complexes The initial course of events in polarizing and organizing asymmetric cell division can be summarized as having three phases: (1) establishment of cell polarity, (2) alignment of the mitotic spindle with cell polarity, and (3) specification of distinct sibling fates.

For phase 1, the BPP complex is already apically located in all ectoderm cells. When some of those cells sink beneath the surface to become neuroblasts, the apical localization of BPP persists. The IPLG complex becomes apically located after the BPP complex. Acting through the evenly distributed DSL complex, the two apical complexes direct the basal localization of MPSB.

For phase 2, the orientation of the spindle relative to the ectoderm is an indirect outcome of the apically located BPP complex, which links the already oriented ectoderm to the IPLG complex. Mitotic spindle microtubules are joined to

the apical IPLG complex by the fly NuMA protein, thus orienting the spindle.

For phase 3, as asymmetric cell divisions commence, each neuroblast renews itself while budding off a smaller daughter GMC in the interior (basal) direction. Different sibling fates are specified by proteins incorporated into the daughter cells. Neuroblasts have stem-cell properties and are determined to retain that stem-cell fate by aPKC, a part of the BPP complex that promotes neuroblast self-renewal. *Brat* and *Prospero*, components of the MPSB complex, are located in the smaller interior (basal) daughter cell and promote GMC differentiation. The G protein component of the IPLG complex activates astral microtubule assembly in a dividing neuroblast, determining the size of the two poles and hence of the daughter cells. Since IPLG is apically localized, the apical daughter cell (a neuroblast) is larger than the basal daughter cell (a GMC).

From this summary, we can see how a set of protein complexes coordinates multiple critical events during asymmetric cell division: localization and activation of asymmetry regulators, differential segregation of cell fate-determining regulatory proteins, orientation of the spindle, and generation of different sized daughter cells.

KEY CONCEPTS OF SECTION 21.4

Regulation of Asymmetric Cell Division

- Asymmetric cell division requires polarization of the dividing cell, which usually entails localization of some cytoplasmic components, and then the unequal distribution of these components to the daughter cells (see Figure 21-26).
- In the asymmetric division of budding yeasts, a myosin-dependent transport system carries *ASH1* mRNA into the bud (see Figure 21-28).
- *Ash1* protein is produced in the daughter cell soon after division and prevents expression of HO endonuclease, which is necessary for mating-type switching. Thus a daughter cell cannot switch mating type, whereas the mother cell from which it arises can (see Figure 21-27).
- Asymmetric cell division in *Drosophila* neuroblasts depends on two apical protein complexes (BPP, IPLG), a basal complex (MPSB), and an evenly distributed complex (DSL). The basal proteins are incorporated into the ganglion mother cell (GMC) and contain proteins that determine cell fate (see Figure 21-30).
- Asymmetry factors exert their influence at least in part by controlling the orientation of the mitotic spindle, so that asymmetrically localized proteins and structures are differentially incorporated into the two daughter cells (see Figure 21-32).
- The atypical protein kinase C (aPKC) in the BPP apical complex phosphorylates the LGL protein, a component of the DSL complex, but can do so only in the apical region, since that is where BPP is located. Nonphosphorylated LGL, which therefore exists only in basal regions, is active in bringing MPSB to the cortex where it requires the actin cytoskeleton to be anchored.

■ The general process of asymmetric cell division and the protein complexes controlling it are highly conserved through evolutionary time.

21.5 Cell Death and Its Regulation

Programmed cell death is a counter-intuitive but essential cell fate. Cell death keeps our hands from being webbed, our embryonic tails from persisting, our immune system from responding to our own proteins, and our brain from being filled with useless electrical connections. In fact, the

majority of cells generated during brain development subsequently die.

Cellular interactions regulate cell death in two fundamentally different ways. First, most if not all cells in multicellular organisms require signals to stay alive. In the absence of such survival signals, frequently referred to as **trophic factors**, cells activate a “suicide” program. Second, in some developmental contexts, including the immune system, specific signals induce a “murder” program that kills cells. Whether cells commit suicide for lack of survival signals or are murdered by killing signals from other cells, death is mediated by a common molecular pathway. In this section, we first distinguish

Video: Cells Undergoing Apoptosis

▲ **FIGURE 21-33 Ultrastructural features of cell death by apoptosis.** (a) Schematic drawings illustrating the progression of morphologic changes observed in apoptotic cells. Early in apoptosis, dense chromosome condensation occurs along the nuclear periphery. The cell body also shrinks, although most organelles remain intact. Later both the nucleus and cytoplasm fragment, forming apoptotic

bodies, which are phagocytosed by surrounding cells. (b) Photomicrographs comparing a normal cell (*top*) and apoptotic cell (*bottom*). Clearly visible in the latter are dense spheres of compacted chromatin as the nucleus begins to fragment. [Part (a) adapted from J. Kuby, 1997, *Immunology*, 3d ed., W. H. Freeman & Co., p. 53. Part (b) from M. J. Arends and A. H. Wyllie, 1991, *Int'l. Rev. Exp. Pathol.* **32**:223.]

programmed cell death from death due to tissue injury, then consider the role of trophic factors in neuronal development, and finally describe the evolutionarily conserved effector pathway that leads to cell suicide or murder.

Programmed Cell Death Occurs Through Apoptosis

The demise of cells by programmed cell death is marked by a well-defined sequence of morphological changes, collectively referred to as **apoptosis**, a Greek word that means “dropping off” or “falling off,” as leaves from a tree. Dying cells shrink and condense and then fragment, releasing small membrane-bound apoptotic bodies, which generally are engulfed by other cells (Figure 21-33; see also Figure 1-19). The nuclei condense and the DNA is fragmented. Importantly, the intracellular constituents are not released into the extracellular milieu where they might have deleterious effects on neighboring cells. The stereotypical changes in cells during apoptosis, like condensation of the nucleus and engulfment by surrounding cells, suggested to early workers that this type of cell death was under the control of a strict program. This program is critical during both embryonic and adult life to maintain normal cell number and composition.

The genes involved in controlling cell death encode proteins with three distinct functions:

- “Killer” proteins are required for a cell to begin the apoptotic process.
- “Destruction” proteins do things like digest DNA in a dying cell.
- “Engulfment” proteins are required for phagocytosis of the dying cell by another cell.

At first glance, engulfment seems to be simply an after-death cleanup process, but some evidence suggests that it is part of the final death decision. For example, mutations in killer genes always prevent cells from initiating apoptosis, whereas mutations that block engulfment sometimes allow cells to survive that would normally die. That is, cells with engulfment-gene mutations can initiate apoptosis but sometimes recover. Engulfment involves the assembly of a halo of actin around the dying cell, triggered by apoptosis proteins that activate Rac, a monomeric G protein that helps regulate actin polymerization (see Figure 17-42). A signal on the surface of the dying cell also stimulates a receptor on neighboring cells, which initiates membrane changes leading to engulfment.

In contrast to apoptosis, cells that die in response to tissue damage exhibit very different morphological changes, referred to as **necrosis**. Typically, cells that undergo this process swell and burst, releasing their intracellular contents, which can damage surrounding cells and frequently cause inflammation.

Neurotrophins Promote Survival of Neurons

The earliest studies demonstrating the importance of trophic factors in cellular development came from analyses of the

developing nervous system. When neurons grow to make connections to other neurons or to muscles, sometimes over considerable distances, more cells grow than will eventually survive. The neurons’ cell bodies are located in the spinal cord and adjacent ganglia, while their processes extend far outside these regions. Those that make connections prevail and survive; those that fail to connect die.

In the early 1900s the number of neurons innervating the periphery was shown to depend upon the size of the tissue to which they would connect, the so-called “target field.” For instance, removal of limb buds from the developing chick embryo leads to a reduction in the number of sensory neurons and motoneurons innervating the bud (Figure 21-34).

▲ EXPERIMENTAL FIGURE 21-34 The survival of motor neurons depends on the size of the muscle target field they innervate. (a) Removal of a limb bud from one side of a chick embryo at about 2.5 days results in a marked decrease in the number of motor neurons on the affected side. In an amputated embryo, normal numbers of motor neurons are generated on both sides (*middle*). Later in development, many fewer motor neurons remain on the side of the spinal cord with the missing limb than on the normal side (*bottom*). Note that only about 50 percent of the motor neurons that originally are generated normally survive. (b) Transplantation of an extra limb bud into an early chick embryo produces the opposite effect, more motor neurons on the side with additional target tissue than on the normal side. [Adapted from D. Purves, 1988, *Body and Brain: A Trophic Theory of Neural Connections*, Harvard University Press, and E. R. Kandel, J. H. Schwartz, and T. M. Jessell, 2000, *Principles of Neural Science*, 4th ed., McGraw-Hill, p. 1054, Figure 53-11.]

Conversely, grafting additional limb tissue to a limb bud leads to an increase in the number of neurons in corresponding regions of the spinal cord and sensory ganglia. Indeed, incremental increases in the target-field size are accompanied by commensurate incremental increases in the number of neurons innervating the target field. This relation was found to result from the selective survival of neurons rather than changes in their differentiation or proliferation. The observation that many sensory and motor neurons die after reaching their peripheral target field suggested that these neurons compete for survival factors produced by the target tissue.

Subsequent to these early observations, scientists discovered that transplantation of a mouse sarcoma tumor into a chick led to a marked increase in the numbers of certain types of neurons. This finding implicated the tumor as a rich source of the presumed trophic factor. To isolate and purify this factor, known simply as nerve growth factor (NGF), scientists used an *in vitro* assay in which outgrowth of neurites from sensory ganglia (nerves) was measured. Neurites are extensions of the cell cytoplasm that can grow to become the long wires of the nervous system, the **axons** and **dendrites** (see Figure 23-2). The later discovery that the submaxillary gland in the mouse also produces large quantities of NGF enabled biochemists to purify and to sequence it. A homodimer of two 118-residue polypeptides, NGF belongs to a family of structurally and functionally related trophic factors collectively referred to as **neurotrophins**. Brain-derived neurotrophic factor (BDNF) and neurotrophin-3 (NT-3) also are members of this protein family.

Neurotrophins bind to and activate a family of receptor tyrosine kinases called *Trks* (pronounced “tracks”). (The general structure of receptor tyrosine kinases and the intracellular signaling pathways they activate are covered in Chapter 16.) Each neurotrophin binds with high affinity to one Trk receptor: NGF binds to TrkA; BDNF, to TrkB; and NT-3, to TrkC. NT-3 can also bind with lower affinity to

both TrkA and TrkB. Binding of these factors to their receptors provides a survival signal for different classes of neurons. As neurons grow from the spinal cord to the periphery, neurotrophins produced by target tissues bind to Trk receptors on the growth cones of the extending axons, promoting survival of neurons that successfully reach targets. In addition, neurotrophins bind to a distinct type of receptor called p75^{NTR} (NTR = neurotrophin receptor) but with lower affinity. However, p75^{NTR} forms heteromultimeric complexes with the different Trk receptors; this association increases the affinity of Trks for their ligands. Depending on the cell type, binding of NGF and BDNF to p75^{NTR} in the absence of TrkA may promote cell death rather than prevent it. (The phenomenon of multiple neurotrophins interacting with multiple similar receptors is comparable to EGF-like ligands and their HER receptors, illustrated in Figure 16-18).

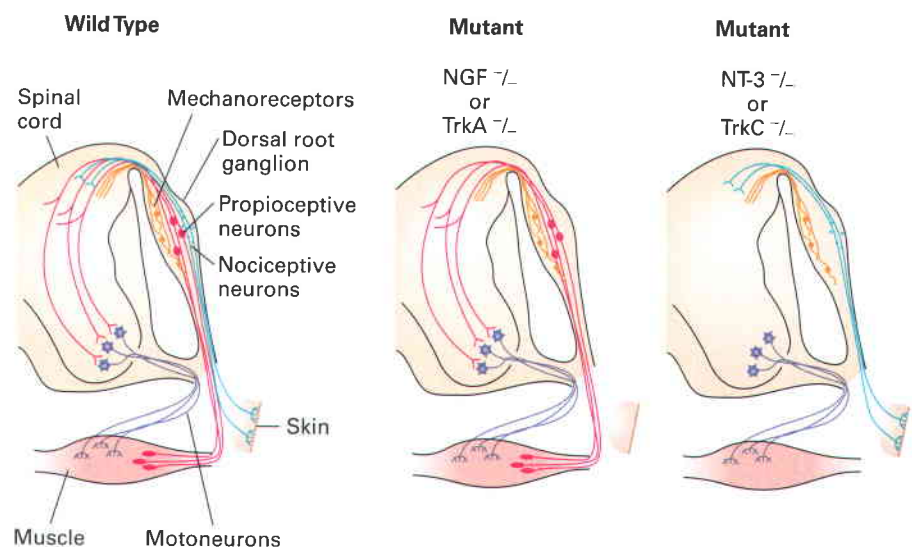

To critically address the role of the neurotrophins in development, scientists produced mice with knockout mutations in each of the neurotrophins and their receptors. These studies revealed that different neurotrophins and their corresponding receptors are required for the survival of different classes of sensory neurons (Figure 21-35). For instance, pain-sensitive (nociceptive) neurons, which express TrkA, are selectively lost from the dorsal root ganglion of knockout mice lacking NGF or TrkA, whereas TrkB- and TrkC-expressing neurons are unaffected in such knockouts. In contrast, TrkC-expressing proprioceptive neurons, which detect the position of the limbs, are missing from the dorsal root ganglion in *TrkC* and *NT-3* mutants.

A Cascade of Caspase Proteins Functions in One Apoptotic Pathway

Neurotrophins and other signals that keep cells alive act upon an evolutionarily conserved cell-death control system. Key insights into the molecular mechanisms regulating cell

► EXPERIMENTAL FIGURE 21-35 Different classes of sensory neurons are lost in knockout mice lacking different trophic factors or their receptors.

In animals lacking nerve growth factor (NGF) or its receptor TrkA, small nociceptive (pain-sensing) neurons (blue) that innervate the skin are missing. These neurons express TrkA receptor and innervate NGF-producing targets. In animals lacking either neurotrophin-3 (NT-3) or its receptor TrkC, large proprioceptive neurons (red) innervating muscle spindles are missing. Muscle produces NT-3 and the proprioceptive neurons express TrkC. Mechanoreceptors (orange), another class of sensory neurons in the dorsal root ganglion, are unaffected in these mutants. [Adapted from W. D. Snider, 1994, *Cell* 77:627.]

Video: Programmed Cell Death in *C. elegans* Embryonic Development

death came from genetic studies using *C. elegans*. Of the 947 nongonadal cells generated during development of the adult hermaphrodite form, 131 cells undergo programmed cell death. Specific mutations have identified four genes whose encoded proteins play an essential role in controlling programmed cell death during *C. elegans* development: *ced-3*, *ced-4*, *ced-9*, and *egl-1*. In *ced-3* or *ced-4* mutants, for example, the 131 “doomed” cells survive (Figure 21-36). The mammalian proteins that correspond most closely to the worm CED-3, CED-4, CED-9, and EGL-1 proteins are indicated in Figure 21-37. In discussing the worm proteins we will include the mammalian names in parentheses to make it easier to keep the relationships clear.

The confluence of genetic studies in worms and studies on human cancer cells first suggested that an evolutionarily conserved pathway mediates apoptosis. The first mammalian apoptotic gene to be cloned, *bcl-2*, was isolated from human follicular lymphomas. A mutant form of this gene, created in lymphoma cells by a chromosomal rearrangement, was shown to act as an oncogene that promoted cell survival rather than cell death (Chapter 25). The chromosome rearrangement joins the coding region of the *bcl-2* gene to an immunoglobulin gene enhancer. The combination results in over-production of Bcl-2 protein that keeps cancer cells alive when, otherwise, they would become programmed to die. The human Bcl-2 protein and

◀ **EXPERIMENTAL FIGURE 21-36 Mutations in the *ced-3* gene block programmed cell death in *C. elegans*.** (a) Newly hatched mutant larva carry a mutation in the *ced-1* gene. Because mutations in this gene prevent engulfment of dead cells, highly refractile dead cells accumulate (arrows), facilitating their visualization. (b) Newly hatched larva with mutations in both the *ced-1* and *ced-3* genes. The absence of refractile dead cells in these double mutants indicates that no cell deaths occurred. Thus CED-3 protein is required for programmed cell death. [From H. M. Ellis and H. R. Horvitz, 1986, *Cell* **91**:818; courtesy of Hilary Ellis.]

worm CED-9 protein are homologous, and a *bcl-2* transgene can block the extensive cell death found in *ced-9* mutant worms even though the two proteins are only 23 percent homologous. Thus both proteins act as regulators that suppress the apoptotic pathway (see Figure 21-37). In addition, both proteins contain a single transmembrane domain and are localized to the outer mitochondrial, nuclear, and endoplasmic reticulum membranes, where they serve as sensors that control the apoptotic pathway in response to external stimuli. As we discuss below, other regulators promote apoptosis.

In the worm apoptotic pathway, CED-3 (caspase 9) is required to destroy cell components during apoptosis. CED-4 (Apaf-1) is a protease-activating factor that causes auto-cleavage of (and by) the CED-3 precursor protein, creating an active CED-3 protease that initiates cell death (see Figure 21-37). Cell death does not occur in *ced-3* and *ced-4* single mutants or in *ced-9/ced-3* double mutants, whereas all cells die during embryonic life in *ced-9* mutants, so the adult form never develops. These genetic studies indicate that the CED-3 and CED-4 are “killer” proteins required for cell death, that CED-9 (Bcl-2) suppresses apoptosis, and that the apoptotic pathway can be activated in all cells. Moreover, the absence of cell death in *ced-9/ced-3* double mutants suggests that CED-9 acts “upstream” of CED-3 to suppress the apoptotic pathway.

The mechanism by which CED-9 (Bcl-2) controls CED-3 (caspase 9) is now known. CED-9 protein, which is normally tethered to the outside of mitochondria, forms a complex with CED-4 (Apaf-1), thereby preventing activation of CED-3 by CED-4. As a result, the cell survives. This mechanism fits with the genetics, which shows that the absence of CED-9 has no effect if CED-3 is also missing (*ced-3/ced-9* double mutants have no cell death). The crystal structure of the trimeric CED-4/CED-9 complex reveals a huge contact surface between each of the two CED-4 molecules and the single CED-9 molecule (Figure 21-38). The large contact

▲ FIGURE 21-37 Evolutionary conservation of apoptosis pathways. Similar proteins, shown in identical colors, play corresponding roles in both nematodes and mammals. (a) In nematodes, the protein called EGL-1 binds to CED-9 on the surface of mitochondria; this interaction releases CED-4 from the CED-9/CED-4 complex. Free CED-4 then activates autoproteolysis of the caspase CED-3, which destroys cell proteins to drive apoptosis. These relationships are shown as a genetic pathway, with EGL-1 inhibiting CED-9, which in turn inhibits CED-4. Active CED-4 activates CED-3. (b) In mammals, homologs of the nematode proteins and other proteins regulate apoptosis. The Bcl-2 protein is similar to CED-9 in promoting cell survival by preventing activation Apaf-1, which is similar to CED-4. Two BH3-only proteins, Bid and Bim, inhibit Bcl-2 to allow apoptosis. Apoptotic stimuli damage mitochondria, leading to release of several proteins that stimulate cell death. In particular, cytochrome c released from mitochondria activates Apaf-1, which in turn activates caspase-9. This initiator caspase then activates effector caspases-3 and -7, eventually leading to cell death. See text for discussion of other mammalian proteins (SMAC/DIABLO and IAPs) that have no nematode homologs. [Adapted from S. J. Riedl and Y. Shi, 2004, *Nature Rev. Mol. Cell Biol.* 5(11):897]

surface makes the association highly specific, but in such a way that the dissociation of the complex can be regulated.

Transcription of *egl-1*, the fourth genetically defined apoptosis regulator gene, is stimulated in response to death signals. Newly produced EGL-1 protein catalyzes the release of CED-4 from CED-9. Both EGL-1 and CED-9 contain a 12-amino acid BH3 domain. Since EGL-1 lacks most of the other domains of CED-9, EGL-1 is called a BH3-only protein. The closest mammalian BH3-only proteins are Bim and Bid. Insight into how

EGL-1 disrupts the CED-4/CED-9 complex comes from the crystal structure of EGL-1 (Bid/Bim) complexed with CED-9 (Bcl-2). In this complex, the BH3 domain forms the key part of the contact surface between the two proteins. CED-9 has a different conformation when bound by EGL-1 than when bound by CED-4. This finding suggests that EGL-1 binding distorts CED-9, making its interaction with CED-4 less probable and less stable. Once EGL-1 causes dissociation of the CED-4/CED-9 complex, the released CED-4 dimer dimerizes again to make a tetramer, which then activates CED-3. Cell death soon follows (Figure 21-39). Evidence for similar events has been found in human cultured cells.

Evidence that the steps described here are sufficient for caspase activation comes from experiments in which the events were reconstituted in vitro (i.e., in solution) with purified components. CED-3, CED-4, a truncated CED-9 that lacked its transmembrane mitochondrial membrane anchor, and EGL-1 were purified, as was a CED-4/CED-9 complex. Purified CED-4 (Apaf-1) was able to accelerate the autocatalysis of purified CED-3 (caspase 9), but addition of the truncated CED-9 (Bcl-2) to the reaction mixture inhibited the autocleavage. When the CED-4/CED-9 complex was mixed with CED-3, autocleavage did *not* occur, but addition of EGL-1 to the reaction restored CED-3 autocleavage.

The effector proteins in the apoptotic pathway, the **cas-pases**, are named because they contain a key cysteine residue in the catalytic site and selectively cleave proteins at sites just C-terminal to **asp**artate residues. Caspases work as homodimers,

▲ FIGURE 21-38 Structure of the CED-4/CED-9 protein complex. The crystal structure has two CED-4 molecules associated with one CED-9 molecule. The C-terminus of CED-9 (dark blue) serves to tether the complex to the mitochondrial membrane. CED-4 is composed of four domains (CARD, α/β folds, winged helix domain, and another helical domain). Each CED-4 molecule has a bound ATP and a Mg^{2+} ion which are visible as a cluster of orange and blue atoms within each subunit. [Based on N. Yan et al., 2005, *Nature* 437:831.]

▲ **FIGURE 21-39 Activation of CED-3 protease in *C. elegans*.**

EGL-1 protein, which is produced in response to signals that trigger cell death, displaces CED-4 dimer from its association with CED-9 on the surface of mitochondria (1). The free CED-4 dimer combines with another to form a tetramer (2), which catalyzes the conversion of the CED-3 zymogen (an enzymatically inactive precursor of a protease) into active CED-3 protease (3). This effector caspase then begins to destroy cell components and thus initiate apoptosis, leading to cell death (4). [Adapted from N. Yan et al., 2005, *Nature* 437:831.]

with one domain of each stabilizing the active site of the other. The principal effector caspase in *C. elegans* is CED-3, while humans have 15 different caspases. All caspases are initially made as procaspases that must be cleaved to become active. Such proteolytic processing of proproteins is used repeatedly in blood clotting, generation of digestive enzymes, and generation of hormones. In vertebrates, initiator caspases (e.g., caspase-9) are activated by autoproteolysis induced by other types of proteins (e.g., Apaf-1), which help the initiators to aggregate. Activated initiator caspases cleave effector caspases (e.g., caspase-3) and thus quickly amplify the total caspase activity level in the dying cell. The various effector caspases recognize and cleave short amino acid sequences in many different target proteins. They differ in their preferred target sequences. Their specific intracellular targets include proteins of the nuclear lamina and cytoskeleton whose cleavage leads to the demise of a cell.

In mammals and flies but not worms, apoptosis is regulated by several other proteins (see Figure 21-37, right). For instance, a family of inhibitor of apoptosis proteins (IAPs), provides another way to restrain both initiator and effector caspases. IAPs have one or more zinc-binding domains that can bind directly to caspases and inhibit their protease activity. (Baculovirus, a type of insect virus, produces a protein that similarly binds to and inhibits caspases, thus preventing an infected cell from committing suicide to stop a viral infection before new viruses can be made.) The inhibition of caspases by IAPs, however, creates a problem when a cell needs to undergo apoptosis. Mitochondria enter the picture once again, since they are the source of a family of proteins, called SMAC/DIABLOs, that inhibit IAPs. After cell injury, SMAC/DIABLOs

released from mitochondria bind to IAPs in the cytosol, thereby blocking the IAPs from binding to caspases. By relieving IAP-mediated inhibition, SMAC/DIABLOs promote caspase activity and cell death. Three other mitochondria-associated proteins—Htra2/Omi serine protease, apoptosis-inducing factor (AIF), and endonuclease G—also help to kill cells upon their release from mitochondria following cell injury. Htra2/Omi cleaves IAPs, thus relieving their restraint of apoptosis. Since this regulation is catalytic, Htra2/Omi is a more powerful antagonist of IAPs than is SMAC/DIABLO. AIF, a flavo-protein that normally acts as a NADH oxidase, is cleaved by proteases and moves to the nucleus where it causes chromosome condensation and DNA fragmentation. These effects are caspase-independent, so not all apoptosis involves caspases.

Pro-Apoptotic Regulators Permit Caspase Activation in the Absence of Trophic Factors

Having introduced the major participants in the apoptotic pathway, we now take a closer look at the workings of the mitochondrial membrane proteins that regulate apoptosis. Although the normal function of CED-9 and Bcl-2 is to suppress the cell-death pathway, other intracellular regulatory proteins promote apoptosis. The first pro-apoptotic regulator to be identified, named Bax, is related in sequence to CED-9 and Bcl-2. Overproduction of Bax induces cell death rather than protecting cells from apoptosis, as CED-9 and Bcl-2 do. Thus this family of regulatory proteins comprises both *anti-apoptotic* members (e.g., CED-9, Bcl-2) and *pro-apoptotic* members (e.g., Bax). All members of this family, which we refer to as the **Bcl-2 family**, are single-pass transmembrane proteins and can participate in oligomeric interactions. In mammals, six Bcl-2 family members prevent apoptosis and nine promote it. Thus the fate of a given cell—survival or death—may reflect the particular spectrum of Bcl-2 family members made by that cell and the intracellular signaling pathways regulating them.

Some Bcl-2 family members preserve or disrupt the integrity of the outer mitochondrial membrane, thereby controlling release of mitochondrial proteins such as cytochrome *c*. In normal healthy cells, cytochrome *c* is localized between the inner and outer mitochondrial membrane, but in cells undergoing apoptosis, cytochrome *c* is released into the cytosol. Overproduction of Bcl-2 blocks release of cytochrome *c* and blocks apoptosis; conversely, overproduction of Bax promotes release of cytochrome *c* into the cytosol and promotes apoptosis. Moreover, injection of cytochrome *c* into the cytosol of cells induces apoptosis. A variety of death-inducing stimuli cause Bax monomers to move from the cytosol to the outer mitochondrial membrane where they oligomerize. Bax homodimers, but not Bcl-2 homodimers or Bcl-2/Bax heterodimers, permit influx of ions through the mitochondrial membrane. It remains unclear how this ion influx triggers the release of cytochrome *c*.

The effect of Bcl-2 family members on the permeability of the mitochondrial outer membrane has been mimicked *in vitro* using vesicles composed of outer mitochondrial membrane. Addition of purified Bax in the presence of a BH3-only protein (e.g., worm EGL-1, vertebrate Bid/Bim) caused permeabilization of the membrane. This biochemical function

of Bcl-2 family members appears to reflect their general ability to alter mitochondrial membranes. In addition to increased permeability, mitochondria normally undergo dramatic changes in their network morphology by fusion and fission during the cell-death process. Bcl-xL, a vertebrate member of the Bcl-2 family, and CED-9 introduced into mammalian cells, can induce mitochondrial fusion. Thus these proteins appear to have profound abilities to engineer the properties of outer mitochondrial membranes.

Once cytochrome *c* is released into the cytosol, it binds to Apaf-1 (the mammalian homolog of CED-4) and promotes activation of a caspase cascade leading to cell death (see Figure 21-37, *right*). In the absence of cytochrome *c*, monomeric Apaf-1 is bound to dATP. After binding cytochrome *c*, Apaf-1 cleaves its bound dATP into dADP and undergoes a dramatic assembly process into a disc-shaped heptamer, a 1.4 megadalton wheel of death called the **apoptosome** (Figure 21-40). The apoptosome serves as an activation machine for initiator and effector caspases.

Some Trophic Factors Induce Inactivation of a Pro-Apoptotic Regulator

We saw earlier that neurotrophins such as nerve growth factor (NGF) protect neurons from cell death. In the absence of trophic factors, however, the nonphosphorylated form of a pro-apoptotic protein called Bad is associated with Bcl-2/

Bcl-xl at the mitochondrial membrane (Figure 21-41a). Binding of Bad inhibits the anti-apoptotic function of Bcl-2/Bcl-xl, thereby promoting cell death. Phosphorylated Bad, however, cannot bind to Bcl-2/Bcl-xl and is found in the cytosol complexed to the phosphoserine-binding protein 14-3-3. Hence, signaling pathways leading to Bad phosphorylation would be particularly attractive candidates for transmitting survival signals.

A number of trophic factors including NGF have been shown to trigger the PI-3 kinase signaling pathway, leading to activation of protein kinase B (see Figure 16-30). Activated protein kinase B phosphorylates Bad at sites known to inhibit its pro-apoptotic activity. Moreover, a constitutively active form of protein kinase B can rescue cultured neurotrophin-deprived neurons, which otherwise would undergo apoptosis and die. These findings support the mechanism for the survival action of trophic factors depicted in Figure 21-41b. In other cell types, different trophic factors may promote cell survival through post-translational modification of other components of the cell-death machinery.

Another mechanism by which neurotrophins can affect apoptosis, this time positively, involves p75^{NTR}, the low-affinity neurotrophin receptor mentioned above. This protein can either promote or inhibit apoptosis depending on the cellular context. In certain neurons, neurotrophin signals such as BDNF stimulate apoptosis by acting through p75^{NTR}. In these neurons, cleavage of p75^{NTR} by a membrane-bound

▲ **FIGURE 21-40 Assembly of the mammalian apoptosome.** In the absence of apoptosis triggers, Apaf-1 exists in the cytosol as an inactive monomer bound to dATP. Apaf-1 contains multiple WD40 repeats, a dATP-binding CED-4 domain, and a CARD domain. Step **1**: When apoptosis is triggered, damage to mitochondria allows release of cytochrome *c*, which binds to Apaf-1. This interaction leads to hydrolysis of the bound dATP to dADP and a change in the conformation of Apaf-1. Step **2**: In its extended conformation,

Apaf-1 assembles into a seven-subunit complex, the apoptosome. Step **3**: Interaction of the apoptosome with the initiator procaspase-9 stimulates the autocleavage and dimerization of the procaspase, which is necessary for its activity. Active caspase-9 then acts upon effector caspases such as caspase-3. Inhibitor of apoptosis proteins (IAPs) are also bound by the apoptosome, although their exact actions there are not understood. [Adapted from Z. T. Schafer and S. Kornbluth, 2006, *Devel. Cell* **10**:549.]

(a) Absence of trophic factor: Caspase activation

▲ **FIGURE 21-41 Proposed intracellular pathways leading to cell death by apoptosis or to trophic factor-mediated cell survival in mammalian cells.** (a) In the absence of a trophic factor, the soluble pro-apoptotic protein Bad binds to the anti-apoptotic proteins Bcl-2 and Bcl-xl, which are inserted into the mitochondrial membrane (1). Bad binding prevents the anti-apoptotic proteins from interacting with Bax, a membrane-bound pro-apoptotic protein. As a consequence, Bax forms homo-oligomeric channels in the membrane that mediate ion flux (2). Through an as-yet-unknown mechanism, this flux leads to the release of cytochrome c into the

(b) Presence of trophic factor: Inhibition of caspase activation

cytosol, where it binds to the adapter protein Apaf-1 (3), promoting a caspase cascade that leads to cell death (4). (b) In some cells, binding of a trophic factor, such as NGF (1) stimulates PI-3 kinase activity, leading to the downstream activation of protein kinase B (PKB), which phosphorylates Bad. Phosphorylated Bad then forms a complex with the 14-3-3 protein (2). With Bad sequestered in the cytosol, the anti-apoptotic Bcl-2/Bcl-xl proteins can inhibit the activity of Bax (3), thereby preventing the release of cytochrome c and activation of the caspase cascade. [Adapted from B. Pettman and C. E. Henderson, 1998, *Neuron* 20:633.]

protease called γ -secretase, releases the receptor's intracellular domain, which is associated with a DNA-binding protein called NRIF. The cleavage of p75^{NTR} leads to the ubiquitination of NRIF and its movement to the nucleus where it stimulates apoptosis, perhaps by regulating transcription. γ -Secretase is the same protease that catalyzes the intramembrane cleavage of the receptor Notch, thus activating it, and also of amyloid precursor protein (APP) in the genesis of Alzheimer's disease (see Figures 16-36 and 16-37).

Tumor Necrosis Factor and Related Death Signals Promote Cell Murder by Activating Caspases

Although cell death can arise as a default in the absence of survival factors, apoptosis can also be stimulated by positively acting *death signals*. For instance, tumor necrosis fac-

tor (TNF α), which is released by macrophages, triggers the cell death and tissue destruction seen in certain chronic inflammatory diseases (Chapter 24). Another important death-inducing signal, the Fas ligand, is a cell-surface protein produced by activated natural killer cells and cytotoxic T lymphocytes. This signal can trigger death of virus-infected cells, some tumor cells, and foreign graft cells.

Both TNF and Fas ligand act through cell-surface "death" receptors that have a single transmembrane domain and are activated when ligand binding brings three receptor molecules into close proximity. The trimeric receptor complex attracts a protein called FADD (Fas-associated death domain), which serves as an adapter to recruit and in some way activate caspase-8, an initiator caspase, in cells receiving a death signal. The death domain found in FADD is a sequence that is present in a number of proteins involved in apoptosis. Once activated, caspase-8 activates other caspases

and the amplification cascade begins. To test the ability of the Fas receptor to induce cell death, researchers incubated cells with antibodies against the receptor. These antibodies, which bind and cross-link Fas receptors, were found to stimulate cell death, indicating that activation of the Fas receptor is sufficient to trigger apoptosis.

KEY CONCEPTS OF SECTION 21.5

Cell Death and Its Regulation

- All cells require trophic factors to prevent apoptosis and thus survive. In the absence of these factors, cells commit suicide.
- Genetic studies in *C. elegans* defined an evolutionarily conserved apoptotic pathway with three major components: membrane-bound regulatory proteins, cytosolic regulatory proteins, and effector proteases called caspases in vertebrates (see Figure 21-37).
- Once activated, apoptotic proteases cleave specific intracellular substrates leading to the demise of a cell. Proteins (e.g., CED-4, Apaf-1), which bind regulatory proteins and caspases, are required for caspase activation (see Figures 21-39 and 21-40).
- Pro-apoptotic regulator proteins (e.g., Bax, Bad) promote caspase activation, and anti-apoptotic regulators (e.g., Bcl-2) suppress activation. Direct interactions between pro-apoptotic and anti-apoptotic proteins lead to cell death in the absence of trophic factors. Binding of extracellular trophic factors can trigger changes in these interactions, resulting in cell survival (see Figure 21-41).
- The Bcl-2 family contains both pro-apoptotic and anti-apoptotic proteins; all are single-pass transmembrane proteins and engage in protein–protein interactions. Bcl-2 molecules can restrain the release of cytochrome *c* from mitochondria, inhibiting cell death, while pro-apoptotic factors stimulate membrane breakdown that allows cytochrome *C* to escape, bind to Apaf-1, and thus activate caspases.
- Binding of extracellular death signals, such as tumor necrosis factor and Fas ligand, to their receptors activates an associated protein (FADD) that in turn triggers the caspase cascade leading to cell murder.

Perspectives for the Future

Cell birth, lineage, and death, which lie at the heart of the development, growth, and healing of an organism, are also central to disease processes, most notably cancer. Few transformations seem more remarkable than the blooming of cell types during development. A lineage beginning with a fertilized egg, a “plain vanilla” 200- μm sphere, produces neurons a yard long, pulsating multinucleate muscle cells, exquisitely light-sensitive retina cells, ravenous macrophages that recognize and engulf germs, and all the hundreds of other cell types. Regulators of cell lineage produce this rich variety by controlling two critical decisions: (1) when and where to

activate the cell cycle (Chapter 20) and (2) whether the two daughter cells will be the same or different. A cell may be just like its parent, or it may embark on a new path.

Cell birth is normally carefully restricted to specific locales and times, such as the basal layer of the skin or the root meristem. Liver regenerates when there is injury, but liver cancer is prevented by restricting unnecessary growth at other times. Cell lineage is patterned by the asymmetric distribution of key regulators to the daughter cells of a division. Some of these regulators are intrinsic to the parent cell, becoming asymmetrically distributed during polarization of the cell; other regulators are external signals that differentially reach the daughter cells. Asymmetry of cells becomes asymmetry of tissues and whole organisms. Our left and right hands differ only as a result of cell asymmetry.

Some cells persist for the life of the organism, but others such as blood and intestinal cells turn over rapidly. Many cells live for awhile and are then programmed to die and be replaced by others arising from a stem-cell population. Programmed cell death is also the basis for the meticulous elimination of potentially harmful cells, such as autoreactive immune cells, which attack the body’s own cells, or neurons that have failed to properly connect. Cell-death programs have also evolved as a defense against infection, and virus-infected cells are selectively murdered in response to death signals. Viruses, in turn, devote much of their effort to evading host defenses. For example, p53, a transcription factor that senses cell stresses and damage and activates transcription of pro-apoptotic members of the *bcl-2* gene family, is inhibited by the adenovirus E1B protein. It has been estimated that about a third of the adenovirus genome is directed at evading host defenses. Cell death is relevant to toxic chemicals as well as viral infections; malformations due to poisons often originate from excess apoptosis.

Failures of programmed cell death can lead to uncontrolled cancerous growth (Chapter 25). The proteins that prevent the death of cancer cells therefore become possible targets for drugs. A tumor may contain a mixture of cells, some capable of seeding new tumors or continued uncontrolled growth, and some capable only of growing in place or for a limited time. In this sense the tumor has its own stem cells, and they must be found and studied, so they become vulnerable to medical intervention. One option is to manipulate the cell-death pathway by sending signals that will make cancer cells destroy themselves.

Much attention is now being given to the regulation of stem cells in an effort to understand how dividing populations of cells are created and maintained. This has clear implications for repair of tissue: for example, to restore damaged eyes, torn cartilage, degenerating brain tissue, or failing organs. One interesting possibility is that some populations of stem cells with the potential to generate or regenerate tissue are normally eliminated by cell death during later development. If so, finding ways to selectively block the death of these cells could make regeneration more likely. Could the elimination of such cells during mammalian development be the difference between an amphibian capable of limb regeneration and a mammal that is not?

Review the Concepts

1. What two properties define a stem cell? Distinguish between a totipotent stem cell, a pluripotent stem cell, and a precursor (progenitor) cell.
2. Where are stem cells located in plants? Where are stem cells located in adult animals? How does the concept of stem cell differ between animal and plant systems?
3. In 1997, Dolly the sheep was cloned by a technique called somatic cell nuclear transfer (or nuclear-transfer cloning). A nucleus from an adult mammary cell was transferred into an egg from which the nucleus had been removed. The egg was allowed to divide several times in culture, then the embryo was transferred to a surrogate mother who gave birth to Dolly. Dolly died in 2003 after mating and giving birth herself to viable offspring. What does the creation of Dolly tell us about the potential of nuclear material derived from a fully differentiated adult cell? Does the creation of Dolly tell us anything about the potential of an intact, fully differentiated adult cell? Name three types of information that function to preserve cell type. Which of these types of information was shown to be reversible by the Dolly experiment?
4. The roundworm *C. elegans* has proven to be a valuable model organism for studies of cell birth, cell lineage, and cell death. What properties of *C. elegans* render it so well suited for these studies? Why is so much information from *C. elegans* experiments of use to investigators interested in mammalian development?
5. How are retroviruses used in tracing experiments that map cell lineages?
6. In the budding yeast *S. cerevisiae*, what is the role of the MCM1 protein in the following?
 - a. transcription of α -specific genes in α cells
 - b. blocking transcription of α -specific genes in α cells
 - c. transcription of α -specific genes in α cells
 - d. blocking transcription of α -specific genes in α cells
7. In *S. cerevisiae*, what ensures that α and α cells mate with one another rather than with cells of the same mating type (i.e., α with α or α with α)?
8. Exposure of C3H 10T $\frac{1}{2}$ cells to 5-azacytidine, a nucleotide analog, is a model system for muscle differentiation. How was 5-azacytidine treatment used to isolate the genes involved in muscle differentiation?
9. Through the experiments on C3H 10T $\frac{1}{2}$ cells treated with 5-azacytidine, MyoD was identified as a key transcription factor in regulating the differentiation of muscle. To what general class of DNA-binding proteins does MyoD belong? How do the interactions of MyoD with the following proteins affect its function? (a) E2A, (b) MEFs, (c) Id.
10. The mechanisms that regulate muscle differentiation in mammals and neural differentiation in *Drosophila* (and probably mammals as well) bear remarkable similarities. What proteins function analogous to MyoD, myogenin, Id, and E2A in neural cell differentiation in *Drosophila*? Based on these analogies, predict the effect of microinjection of *myoD* mRNA on the development of *Xenopus* embryos.
11. Predict the effect of the following mutations on the ability of mother and daughter cells of *S. cerevisiae* to undergo mating-type switching following cell division:
 - a. loss-of-function mutation in the HO endonuclease
 - b. gain-of-function mutation that renders HO endonuclease gene constitutively expressed independent of SWI/SNF
 - c. gain-of-function mutation in SWI/SNF that renders it insensitive to Ash1
12. Asymmetric cell division often relies on cytoskeletal elements to generate or maintain the asymmetric distribution of cellular factors. In *S. cerevisiae*, what factor is localized to the bud by myosin motors? In *Drosophila* neuroblasts, what factors are localized apically by microtubules?
13. How do studies of brain development in knockout mice support the statement that apoptosis is a default pathway in neuronal cells?
14. What morphologic features distinguish programmed cell death and necrotic cell death? TNF and Fas ligand bind cell-surface receptors to trigger cell death. Although the death signal is generated external to the cell, why do we consider the death induced by these molecules to be apoptotic rather than necrotic?
15. Predict the effects of the following mutations on the ability of a cell to undergo apoptosis:
 - a. mutation in Bad such that it cannot be phosphorylated by protein kinase B (PKB)
 - b. overexpression of Bcl-2
 - c. mutation in Bax such that it cannot form homodimers

One common characteristic of cancer cells is a loss of function in the apoptotic pathway. Which of the mutations listed above might you expect to find in some cancer cells?

16. How do IAPs (inhibitor of apoptosis proteins) interact with caspases to prevent apoptosis? How do mitochondrial proteins interact with IAPs to prevent inhibition of apoptosis?

Analyze the Data

The immortal-strand hypothesis postulates that when a stem cell divides asymmetrically to produce one “new” stem cell and one progenitor cell, the new stem cell receives the sister chromatids containing the oldest strand of DNA (the immortal strand). The other daughter cell, a progenitor cell that eventually gives rise to differentiated cells, receives the sister chromatids containing more recent DNA strands (see diagram below). If the immortal-strand mechanism actually operates, it would prevent the accumulation of mutations in adult stem cells that otherwise would occur during each round of DNA replication.

Muscle satellite cells are progenitors for myoblasts and are the source of cells that result in muscle growth after birth and muscle repair after injury. The satellite cells can replenish themselves, suggesting that they also have properties of stem cells. To test the immortal-strand

hypothesis, researchers recently conducted the following studies:

a. Satellite cells were isolated from mouse muscle fibers and cultured *in vitro* in the presence of BrdU, a nucleotide analog that is incorporated into DNA during replication. After 4 days in BrdU, all satellite cells in the culture were extensively labeled with BrdU (pulse), as expected if these cells underwent symmetric divisions. The cells were then incubated for 18 hours in the absence of BrdU (chase), a period of time that corresponds to approximately two cell divisions in these cells. The images below show two examples of muscle satellite cells undergoing division after this 18-hr incubation in the absence of BrdU. The blue labeling (Hoechst) shows total DNA, the red labeling shows where BrdU-containing DNA is located.

The majority of the cells appear like the dividing cell in the top panel, but about 1.5 percent of dividing cells appear like that in the lower panel. Can you explain these observations? Given that mice have 40 chromosomes, could the segregation of the BrdU-labeled sister chromatids, observed in the lower panel, have occurred by chance?

b. Satellite cells were subjected to a BrdU pulse-chase experiment similar to that described in part (a) above and then were assessed for the production of Numb, a protein whose presence or absence allows two daughter cells to adopt different developmental fates. The micrographs below show a dividing cell stained for Numb (green) and for BrdU-containing DNA (red). What do you expect to be the outcome of the daughter cell that acquires Numb? How might you determine if Numb is involved in generating co-segregation of the older DNA strands?

c. Suppose you conducted a pulse-chase experiment using an established cultured cell line, but asymmetric divisions like that observed in the lower panel in part (a) above were not observed. Explain this result.

From a single cell to a human embryo. Twenty hours after the fertilization of a human egg, the male and female pronuclei are about to fuse and combine the genetic information from father and mother. Forty-six days later the embryo, 2 cm long, is beginning to develop organs and tissues, nourished by blood entering through the umbilical cord. [Courtesy of The Lennart Nilsson Award Board.]

THE MOLECULAR CELL BIOLOGY OF DEVELOPMENT

Just as notes and chords blend into a symphony, genes, proteins, and cells act as an integrated system during **embryogenesis**, the development of an embryo. Signals flow within and between cells, and massive waves of gene expression allow thousands of types and shapes of cells to form (Chapters 7, 15, 16). For normal embryogenesis, the cell cycle must be regulated, as described in Chapter 20, so that cell growth and division occur at the right times and places; cell lineages like those described in Chapter 21 must be organized in time and space; mechanisms described in Chapters 17–19 must organize cells into tissues, organs, and whole bodies; and cell death (Chapter 21) must be programmed so that the webbing—not the fingers—is removed.

In this chapter we explore the regulation of early-stage animal embryos to observe developmental mechanisms in context. We concentrate on insects and mammals, with some examples from other animal species, as well as plants. After a brief summary of early development, we describe how eggs and sperm are made, how fertilization occurs, and the special genetic properties of early mammalian cells. Then we look at the earliest cell divisions in mammalian development and the creation of different layers of tissues. The formation of repeating segments in animal embryos and the genes that eventually cause those segments to differ are discussed next. We also examine several particularly informative aspects of later animal development, including formation of the left-right asymmetry of the body, control of cell fates in the early nervous system, and the patterning of limbs. As we cover various topics, we will see how different experimental approaches—lineage tracing, genetic screens, mosaic animals, manipulations of signaling proteins, and transplantation—

have been used to discover and analyze key molecular and cellular events that build animals.

Let's start by thinking about a simple situation in which a sheet of cells has formed through cell division, but all the cells are identical. To form a working tissue, each cell has to do its job. Some may divide, some may bend, some may send out a signal. Each cell must somehow learn its location and fate, and start to differentiate appropriately. **Differentiation** may entail activation of certain genes, production of particular proteins, an increase or decrease in cell division, changed shape, changed surface properties and adhesion to other cells, the release of secreted signals, the acquisition of electrical activity, polarization along one or more axes,

migration, or a combination of any of these. A mistake in any aspect of cell differentiation early in development can be fatal to the organism.

The fascination of developmental cell biology lies in discovering how the integrated system of development works and why it is so successful despite variations in environment, inherited genes, cell numbers, and nutrition. At the same time, this field offers a new way to explore evolution and human origins: how animal forms and species arose, are maintained, and change. In addition, many diseases are most readily understood in the context of normal developmental processes gone awry. And it all begins with a single cell!

22.1 Highlights of Development

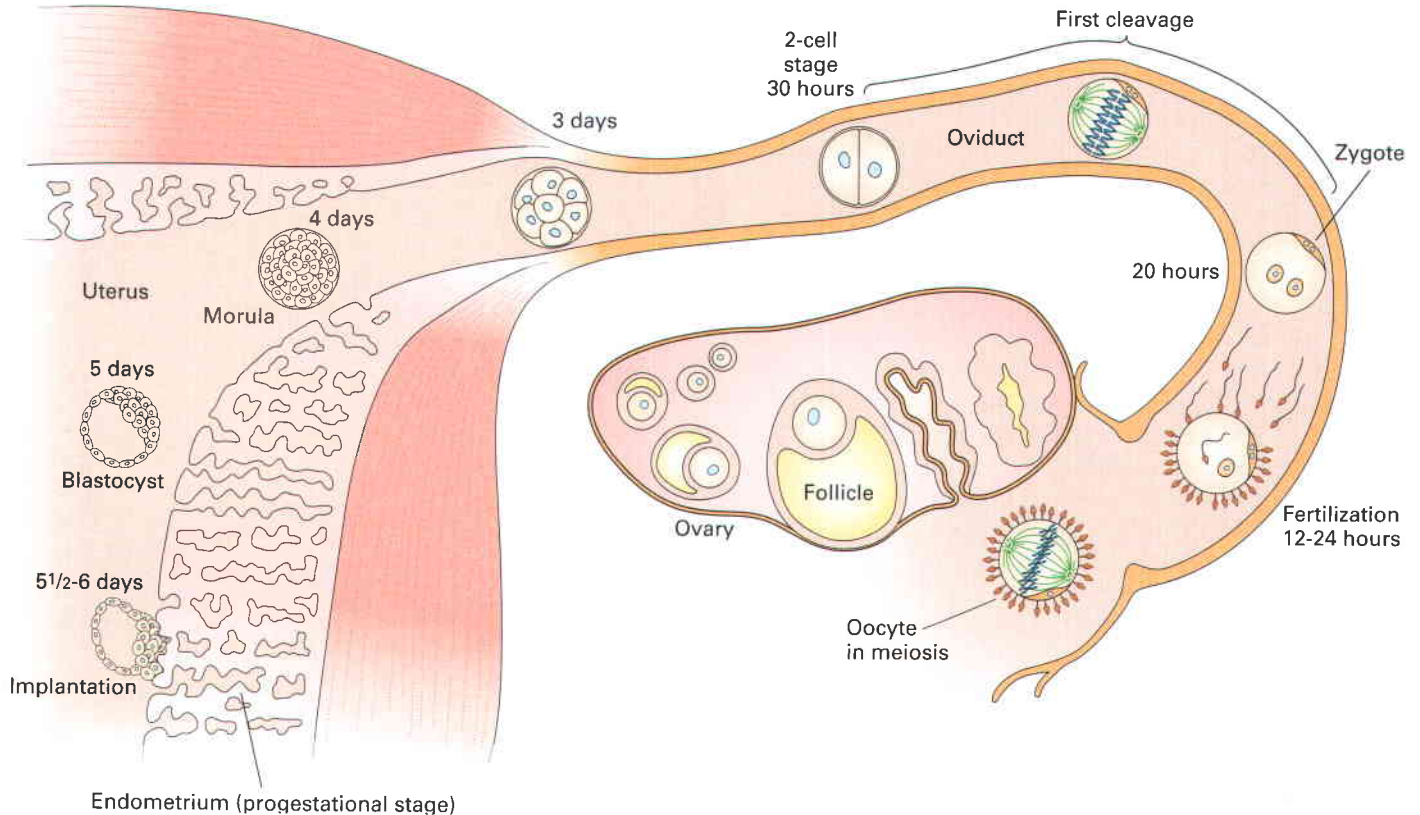

Single-celled organisms can go through complex developmental life cycles during which their shapes and behaviors may change dramatically. An example is the life cycle of the malaria plasmodium discussed in Chapter 1 (see Figure 1-4). In this chapter, however, we concentrate on development of multicellular animals. The earliest stages of animal development accomplish several crucial goals: combination of maternal and paternal genomes in a new organism; an increase in the number of cells; formation of three main layers of cells, the first step in creation of different cell and tissue types; and the laying out of the main organization of the embryo—front to back, head to tail, and left to right.

Development Progresses from Egg and Sperm to an Early Embryo

The development of a new organism begins with the fusion of male and female **gametes**: an egg (*oocyte*), carrying a set of chromosomes from the mother, and a *sperm*, carrying a set of chromosomes from the father. The gametes, or sex cells, are **haploid** because they have gone through **meiosis** and thus contain only one set of chromosomes (see Figure 5-3). They combine in a process called fertilization, creating the initial single cell, the **zygote**, that has two sets of chromosomes (one maternal and one paternal) and is therefore **diploid**. The zygote begins to divide in a process called **cleavage**, which produces a mass of cells that often look rather similar to each other (Figure 22-1). The progeny of these initial cells will gradually become different, forming all the organs and tissues.

Early in embryogenesis the cells divide into two distinct sets: **germ-line cells**, which will give rise to gametes, and **somatic cells**, which will form most of the body but are not passed on to future progeny. Germ-line cells are carriers of genetic alterations and, in some cases, inherited disease states, but anything that happens to the DNA of somatic cells cannot be passed on to future generations.

In order for a functioning organism to develop, the embryo must become **polarized**. That is, cells on one side (left-right or head-tail or front-back) behave differently than cells on another side. The information that sets the polarities of

▲ **FIGURE 22-1** Early stages in human development. This drawing depicts fertilization, cleavage (cell divisions), and implantation in the context of the oviduct and uterus where these

events occur. The timing is indicated in terms of hours or days after release of an egg from the ovary. [Adapted from T.W. Sadler, *Langman's Medical Embryology*, 9th ed., Lippincott Williams and Wilkins, Figure 2-11.]

the embryo may be provided in the form of localized proteins or RNA molecules in the egg or the location where the sperm enters the egg, which can cause local changes that begin the process of polarization. Alternatively, a random asymmetry of the early embryo may become fixed as the embryo's final polarity.

To create the initial tissue layers, sheets of cells fold and some cells move inward, a process called **gastrulation**. The embryo becomes more three-dimensional and consists of three **germ layers**: the ectoderm ("outer skin"), the mesoderm ("middle skin"), and the endoderm ("inner skin"). Although the concept of three germ layers is really an oversimplification of the more complex truth, each layer gives rise to particular tissues and structures, even in rather diverse animals, and thus the terms have had enough value to persist (see Figure 21-3). The cell movements that generate the germ layers require that the surface properties of cells change to release or cement connections between cells. Cells in the early embryo can form either loose-knit masses classified as **mesenchyme** or sheets called **epithelia**. In the course of development, cells can go back and forth between these two states. Epithelia are usually polarized, one side of the sheet being described as basal and the other apical.

Early in development, cells begin to signal using the various types of secreted proteins discussed in Chapters 15 and 16. For signaling to be useful in creating new cell types, some cells must make the signal, while others make the receptor. Cells that are able to sense and respond to a signal are described as **competent**. The polarization of the early embryo that begins to make cells different allows some cells to become signal producers and other cells to become signal receivers; some cells both produce and receive signals. **Induction** is the process whereby a signal sent from one cell or set of cells influences the fates of other cells. For example, a signal may induce precursor cells to form neural tissue.

Embryonic cells are constantly sampling their local environment to see how it conforms to their genetically programmed expectations. The absence of an expected signal or the presence of an inappropriate one can cause a cell to die, divide, move, change identity, or change shape. One signal can inform a cell about its location along the dorsal-ventral (back-front) body axis, while another tells the cell its anterior-posterior (head-tail) position. Yet a third signal could tell the cell to commence mitosis. A cell can *integrate* multiple signals and thus respond simultaneously to different signals. In some cases, a cell's final response will not be a simple summation of the multiple signals. Instead, one signal may modify the cell's response to another signal. In addition to local signals, long-distance signals such as hormones, which can reach much or all of a developing or mature animal, coordinate the timing of events, stimulating growth or triggering other changes.

Some developmental signals act in a concentration-dependent manner. That is, the receiving cells respond in one way to high signal levels and in a different way to low signal levels. Generally, cells close to the source of a signal will be exposed to high levels, and cells farther away to lower levels. Thus the location of the source, the location of cells that

have the relevant receptor, and the ability of the signal to move through tissue will govern where particular responses to a concentration-dependent signal occur.

As the Embryo Develops, Cell Layers Become Tissues and Organs

Molecular cell biology underlies the ways individual cells differentiate into different cell types, say those forming a kidney or the skin. Critical to cell differentiation is activation of specific genes, such as the genes that encode various keratins, the fibrous proteins of the skin. In addition to the differential gene expression that creates and characterizes a *type* of cell, the formation of tissues and organs depends on the proper *arrangements* of cells. For example, the light-sensitive cells of the eye must be arrayed on the retina surface, and muscle cells must be arranged so that they can move the lens and focus the image on the retina. Thus formation of organs and tissues depends on communication between cells as well as movements and rearrangements of cells. The branching patterns of blood vessels, and the proper connections between nerves and muscles, are possible because developing cells communicate.

The process of forming all the working parts of the body—the heart, liver, kidney, gonads, lungs, etc.—is known as **organogenesis**. Organogenesis often involves bending and folding layers of cells. An epithelial sheet of cells can bend if cells along a stripe down the middle all constrict their apical end, while the other end is relaxed. Such coordinated changes in cytoskeletal shape and organization are crucial in organogenesis, as are signals between different tissue layers. Circulatory systems and hearts typically undergo organogenesis early, since abundant oxygen must be delivered to every cell.

Distinct cell types from distinct lineages collaborate to form an organ. The skin has epidermis from the ectoderm and dermis from the mesoderm; the lens of the eye derives from one cell lineage and retina from another; limbs are made of muscle and bone and nerves and skin. Signals between tissues of different origins allow formation of proper structures at the right times and places.

The organization of whole tissues, known as **pattern formation**, underlies much of the beauty of the natural world: flowers, butterfly wings, faces, coral reef fish; warning colors, camouflage, and mimicry. Symmetric patterns are common in animals: Our left hand mirrors our right hand, for instance. Both hands are made of the same stuff; only the pattern differs. Patterns often include repeating units like body segments or vertebrae or fingers. Variations on the repeats confer different functions, like opposable thumbs. Symmetry breaking, or asymmetric patterning, is crucial to development of many animals, including humans. For example, our growing heart twists in a particular helical way to begin forming heart chambers.

Although this chapter concentrates on development of the embryo, development continues after birth of an animal. Many tissues continue to grow and develop until the adult stage is reached. And, as discussed in Chapter 21, some

tissues such as skin, blood, hippocampus (part of the brain), intestinal lining, and the eyes of fish continuously regenerate even in adults, or regenerate after injury (e.g., liver). In many animals, ecological complexities such as changing conditions or migrations trigger *metamorphosis*. Insect embryos, for instance, metamorphose to become larvae (juveniles), which subsequently metamorphose to become adults; salmon metamorphose to adapt from fresh to salt water.

Aging also can be viewed as a developmental process. As an animal ages, many cell types undergo physiological changes that underlie changes in organ and tissue functions. That aging is a genetically programmed aspect of development is apparent from observations of seemingly similar tissues aging at different rates in different animal species. Aging can also be strongly influenced by environmental factors, so as in many developmental processes there is an interplay between genes, nutrition, and experience.

Genes That Regulate Development Are at the Heart of Evolution

Evolution is a process of change in the forms and abilities of living organisms over generations. Just as no two humans are identical (even “identical” twins are not), differences are found within any group of organisms. Occasionally the differences confer an advantage in reproduction. In fact the process of evolution has been employed by farmers and others for thousands of years, selecting plants and animals with useful properties and selectively breeding those. The enormous variation among strains of dogs, for example, has resulted from selection by humans over perhaps 10,000–20,000 years. The fossil record shows that natural selection, which has operated for hundreds of millions of years, has led to changes far greater than the differences among dogs. Changes in climate, geology, location and the presence of other creatures created new ecological niches and animals evolved in ways that allowed life in many of them.

Since the form and functions of any organism are controlled by an increasingly well-understood battery of development-regulating genes, changes in such genes must account for the heritable changes that underlie the evolution of different animals and plants. However, the mutations underlying inherited evolutionary changes, whether the selection was by humans or by natural causes, generally have been unknown in the past. This is beginning to change with the current surge of knowledge about which genes matter to the development of tissues and organs, along with the increasing availability of DNA sequences from many organisms. These advances are revealing the molecular genetic differences that distinguish varieties of plants and animal.

Many changes in genes are harmful, and changes in genes that control growth and/or development might be expected to have major deleterious effects. Indeed, many inherited human genetic syndromes (a syndrome is a group of disease features that tend to occur together) involving birth defects or cancer have been linked to developmental genes.

The conservation of most types of developmentally important proteins across diverse animal species indicate that these proteins existed in animal ancestors half a billion years ago. In many cases, particular proteins have remained engaged in generating a particular organ or tissue type over all that time, despite the dramatic morphological distinctions between, say, insect and mammalian hearts. The similarities in gene functions among animal species have allowed inferences to be drawn about human gene functions and disease processes based on information from many different species.

Evolution of animal form could in principle depend upon the emergence of new genes and new proteins, but relatively few such cases are known. Instead changes in body form over generations appear to be due primarily to alterations in hundreds of thousands of short regulatory DNA sequences that influence the transcription of genes and the processing of RNA. Most of the working protein “hardware” is similar in animals of vastly different morphology, but the “software” can change readily and rapidly.

KEY CONCEPTS OF SECTION 22.1

Highlights of Development

- The paternal and maternal genomes come together in the fertilized egg.
- Germ-line cells make eggs and sperm and some are inherited by progeny; somatic cells make all the rest of the body but are not passed on to progeny.
- During embryogenesis, a largely symmetric fertilized human egg becomes an early embryo that is asymmetric along the anterior-posterior (head-tail), left-right, and dorsal-ventral (back-front) axes (see Figure 22-1).
- An early embryo forms three initial layers of cells—endoderm, mesoderm, and ectoderm—that give rise to different tissues and organs.
- Embryonic cells communicate with each other via secreted protein signals that bind to receptors on receiving cells, triggering changes in the receiving cells that lead to their differentiation into specific cell types. This process, in which one type of cell, or group of cells, sends a signal that affects the fates of other cells, is called induction.
- Organogenesis is the process of forming all the working tissues and organs of the body.
- Pattern formation is the process of organizing the shapes, sizes, and colors of tissues and organs during development.
- Many genes have been identified that control development, and damage to such genes can lead to birth defects, cancer, or tissue degeneration.
- Many types of development-regulating genes are evolutionarily conserved. Not only can the genes be identified in a wide spectrum of animal types, but in many cases a gene plays a similar role in seemingly very different animals. This reflects the evolution of animals from common ancestors.

22.2 Gametogenesis and Fertilization

Whether in the comfort of a womb or the shelter of a shell, embryos confront similar challenges: starting with the right chromosomes, obtaining nutrition, organizing growth, making diverse cell types, and creating pattern.

Germ-line Cells Are All That We Inherit

The setting aside of germ-line cells early in development has been hypothesized to protect chromosomes from damage by reducing the number of rounds of replication they undergo or by allowing special protection of the cells that are critical to heredity. Whatever the reason, early segregation of the germ line is widespread (though not universal) among animals. In contrast, plants do nothing of the sort: Most meristems, the groups of dividing cells at the tips of growing shoots and roots, can give rise to germ-line cells. One consequence of the early segregation of germ-line cells is that the loss or rearrangement of genes in somatic cells cannot affect the inherited genome of a future zygote.

Fruit flies (*Drosophila*) were critical in working out many fundamental aspects of chromosome behavior beginning almost a century ago. Now they are used to investigate development, genomics, and molecular cell biology, and a variety of mutant flies serve as models of human diseases. These model organisms also are useful for examining gametogenesis, the creation of eggs (*oogenesis*) and sperm (*spermatogenesis*).

Drosophila oogenesis begins with a stem cell that divides asymmetrically to generate a single germ-line cell (or simply **germ cell**), which divides four times to generate 16 cells. One of these cells will complete meiosis (see Figure 5-3), becoming an oocyte; the other 15 cells become *nurse cells*, which synthesize proteins and mRNAs that are transported through cytoplasmic bridges to the oocyte (Figure 22-2). The

proteins and mRNAs provided by the nurse cells are necessary for maturation of the oocyte and for the early stages of embryogenesis; they also play a key role in organizing the main body of a fly. At least one-third of the *Drosophila* genome is represented in the mRNA contributed by the mother to the oocyte, a substantial dowry. Each group of 16 cells is surrounded by a single layer of somatic cells called the *follicle*, which deposits the eggshell. The mature oocyte, or egg, is released into the oviduct, where it is fertilized; the fertilized egg (the zygote) is then laid.

In mammals, about 2,500 germ-line cell precursors, the *primordial germ cells* (PGCs) form during gastrulation and migrate to a part of the abdominal cavity's mesoderm where the gonad (ovary or testis) will eventually form. These primordial germ cells produce Kit protein, a cell-surface receptor for Steel, a mitogenic protein signal secreted from cells along the path of PGC migration. Thus, as the primordial germ cells migrate, they divide under the influence of Steel. After arriving at their destination in the gonads, primordial germ cells prepare for either oogenesis or spermatogenesis.

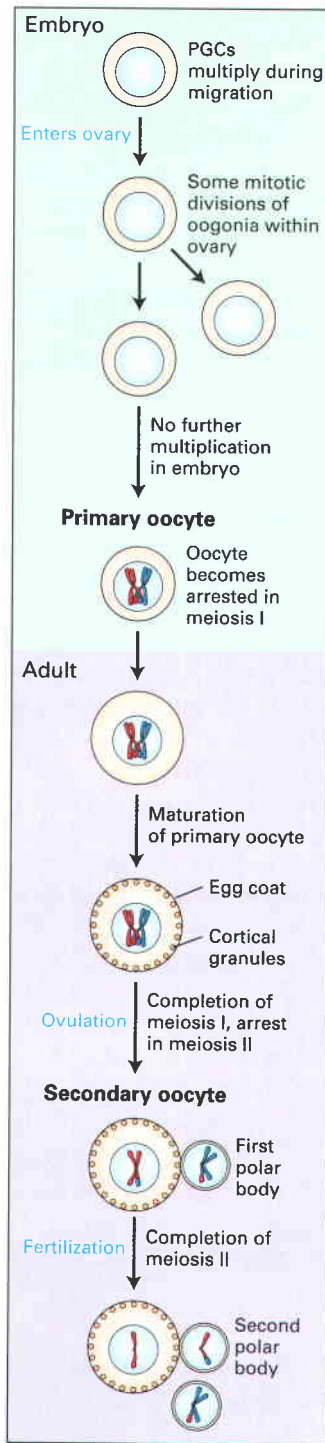

As shown in Figure 22-3a, primordial germ cells in the developing human ovary continue dividing during months 2–7 of gestation to produce about six million *primary oocytes*. Of these, about 400,000 survive to puberty and about 500 will be ovulated during a lifetime. The primary oocytes begin meiosis but are arrested at the first meiotic prophase. Because of this prophase arrest, primary oocytes are tetraploid, which provides extra copies of the genome to help provision the unusually large egg cell. Some oocytes remain in the first meiotic prophase for nearly 50 years. Puberty triggers rapid growth of primary oocytes, which will eventually be about 200 μm in diameter. Meiosis continues at ovulation, but is completed only after fertilization. Each meiosis yields a single mature oocyte, or egg cell.

▲ **FIGURE 22-2** *Drosophila* oogenesis. A single germ-cell precursor gives rise to fifteen nurse cells (green) and a single oocyte (yellow) early in oogenesis (1). The early oocyte is about the same size as the neighboring nurse cells; the follicle, a layer of somatic cells, surrounds the oocyte and nurse cells. The nurse cells begin to synthesize mRNAs and proteins necessary for oocyte maturation, and the follicle cells begin to form the eggshell. Midway through oogenesis (2), the oocyte has increased in size considerably. The mature egg (3) is surrounded by the completed eggshell (gray). The

nurse cells have been discarded, but mRNAs synthesized and translocated to the oocyte by the nurse cells function in the early embryo. Polar granules located in the posterior region of the egg cytoplasm mark the region in which germ-line cells will arise. The asymmetry of the mature oocyte (e.g., the off-center position of the nucleus) sets the stage for the initial cell-fate determination in the embryo. After its release into the oviduct, fertilization of the egg triggers embryogenesis. [Adapted from A. J. F. Griffiths et al., 1993, *An Introduction to Genetic Analysis*, 5th ed., W. H. Freeman and Company, p. 643.]

(a) Oogenesis

(b) Spermatogenesis

◀ **FIGURE 22-3 Mammalian gametogenesis.** In both males and females, the process of gamete formation begins in the embryo and is completed in the adult. (a) Oogenesis begins with proliferation of primordial germ cells (PGCs) in the early embryo and their accumulation at the site where the ovary will form. Primary oocytes become arrested in meiosis I until puberty. Upon ovulation, an oocyte completes meiosis I and arrests in meiosis II. Meiosis II is completed if the oocyte is fertilized. Each meiosis yields a single haploid oocyte; the other products of meiosis become polar bodies, which are nonfunctional. (b) Spermatogenesis also begins with PGCs multiplying in the embryo and accumulating in the developing testis. Unlike oocyte precursors, sperm precursors (spermatogonia) arrest in G₁ of the cell cycle and do not commence meiosis until after birth. Subsequent mitotic and meiotic cell divisions are incomplete, yielding haploid spermatids with bridged cytoplasm (syncytia). Spermatids differentiate into mature sperm in a process called spermiogenesis (see Figure 22-4). [Adapted from L. Wolpert et al., 2001, *Principles of Development*, 2nd ed., Oxford University Press, Figure 12-18.]

cytoplasmic bridges. Each meiosis produces four haploid gametes, or *spermatids*, connected to each other by cytoplasmic bridges. These bridges allow synchronization of germ-cell maturation and sharing of substances between cells; thus the haploid cells resulting from meiosis can share products of the unique X or Y chromosome each haploid cell carries.

Spermatids undergo a dramatic differentiation process (*spermiogenesis*) that generates mature sperm cells (Figure 22-4). The Golgi apparatus moves to one end of the cell to form the *acrosomal cap* over the nucleus, while the flagellum begins to form at the other end of the cell. Mitochondria coalesce near the base of the flagellum, ready to provide ATP for swimming. Much of the cytoplasm is extruded, the cytoplasmic bridges are lost, and the nucleus condenses to a mere shadow of its former self, driven by the arginine-rich protein protamine, which displaces the normal histones from the chromatin. The sperm is ready to go.

In humans, formation of a sperm cell from a spermatocyte takes about two months. Human males produce about 10⁸ sperm/day and more than 10¹² in a lifetime. Human sperm are about 50 μm long, but *Drosophila* sperm are considerably larger. Amazingly, the sperm in one fly species are about 5.8 cm long, which is twenty times longer than the male fly that produces them! A mature sperm consists of a head, containing the acrosome and condensed nucleus, and a flagellum tail. The tail contains a complex structure, the **axoneme**, composed of microtubules and dynein motor proteins whose movements propel the sperm toward the egg (see Figures 18-29–18-31). Mitochondria at the base of the tail provide energy in the form of ATP to power axoneme movement.

 Mutations that damage motor proteins in sperm flagella can cause sterility. In the inherited disease Kartagener's syndrome, for instance, defects in the dynein arms of the axoneme (sometimes caused by mutation of the dynein gene itself) cause immotile cilia and flagella. The consequences include male infertility and situs inversus.

▲ **FIGURE 22-4 Spermiogenesis.** The differentiation of a spermatid (1) into a mature sperm cell (4) involves a series of dramatic morphological changes. At one end, the acrosomal cap forms over the nucleus, which becomes highly condensed. At the other end, the flagellum elongates, and much of the cytoplasm around its base is lost, leaving a sheath of mitochondria. Although not depicted, each spermatid is connected by cytoplasmic bridges to adjacent spermatids (see Figure 22-3b). These are severed during spermiogenesis, so each mature sperm cell can move independently. [Adapted from K. Kalthoff, 1996, *Analysis of Biological Development*, McGraw-Hill, Figure 3.9, and L. Wolpert et al., 1998, *Principles of Development*, 1st ed., Oxford University Press, Figure 12.21.]

Situs inversus is a birth defect in which the heart and other organs are located on the wrong side of the body. This abnormality results from the immotility of cilia that would normally polarize the left-right axis of the body during gastrulation, as we shall see in Section 22.3. ■

Several critically important events happen during gametogenesis. In both sexes meiosis reduces the number of chromosomes to a haploid set. The sorting of chromosomes that goes on is itself an extraordinary generator of variation. Since there are 23 pairs of chromosomes in humans and there is an equal chance of retaining either one of a pair in a particular gamete, 2^{23} different possible combinations of chromosomes could emerge from meiosis. Among human populations, there is single nucleotide sequence heterogeneity about once in a thousand base

pairs, so an average size human chromosome of about 130×10^6 bp will have 130,000 differences from its homolog. Add to this diversity the process of recombination (about one crossover per chromosome) that gives rise to new combinations of sequences, and the diversity is striking. Male gametogenesis also governs the sex of the next generation: Sperm carrying an X chromosome produce female offspring, while those carrying a Y chromosome produce male offspring.

Fertilization Unifies the Genome

Fertilization can be a spectacular event, as when all the coral animals of the Great Barrier Reef of Australia release eggs and sperm on the same night once each year at a full moon. The process of *fertilization*, which results in union of an egg and sperm, comprises several challenging events: penetration of an egg by a single sperm cell, assembly of a diploid (no more and no less) genome, completion of the egg's meiotic division, and initiation of a proper program of gene activation. Sperm were first described in the late 1600s, and eggs, being much larger, were recognized much earlier. Fertilization itself, however, was not directly observed and documented until the late 1800s. Pioneering studies on fertilization were done with sea urchin eggs and sperm because both eggs and sperm are easy to isolate, grow in culture, and watch. Observation of the fusion of the haploid pronuclei of the egg and sperm helped to dispel the earlier idea that sperm were contaminating animals living in semen.

It is remarkable that a sperm is ever able to reach and penetrate an egg. In humans, for instance, each sperm is competing with more than 100 million other sperm for a single egg, and it must swim a long distance to approach the egg. Moreover, the egg has multiple surrounding layers that restrict sperm entry. Although sperm are streamlined for speed and swimming ability, only a few dozen reach the egg in the oviduct (see Figure 22-1). The flagellum of human sperm contains about 9000 dynein motors that flex microtubules in the axoneme, causing successive bending that propels the sperm forward (see Figure 18-31). Estimates of the force produced by a single dynein motor protein range from 1–6 piconewtons (pN). Since 1 pN is enough to lift a red blood cell, a sperm clearly packs a lot of motor power.

The acrosomal cap (or simply, acrosome), found at the tip of the sperm head, is a membrane-bound compartment specialized for interaction with the oocyte. The acrosome's membrane is just under the plasma membrane at the sperm head; on the other side of the acrosome, its membrane is juxtaposed to the nuclear membrane (see Figure 22-4). Inside the acrosome are soluble enzymes including hydrolases and proteases. Once a sperm approaches an egg, it must first penetrate a layer of cumulus cells that are derived from the ovarian follicle where the oocyte matured. The sperm then encounters the *zona pellucida*, a gelatinous extracellular matrix, $\approx 6 \mu\text{m}$ thick, that surrounds the egg (Figure 22-5a). The zona pellucida is composed largely of three glycoproteins

◀ **FIGURE 22-5 Gamete fusion during fertilization.**

(a) Mammalian eggs, such as the mouse oocyte shown here, are surrounded by a ring of translucent material, the zona pellucida, which provides a binding matrix for sperm. The diameter of a mouse egg is $\approx 70 \mu\text{m}$, and the zona pellucida is $\approx 6 \mu\text{m}$ thick. The polar body is a nonfunctional product of meiosis. Scale bar = $30 \mu\text{m}$. (b) In the initial stage of fertilization, the sperm penetrates a layer of cumulus cells surrounding the egg (1) to reach the zona pellucida. Interactions between GalT, a protein on the sperm surface, and ZP3, a glycoprotein in the zona pellucida, trigger the acrosomal reaction (2), which releases enzymes from the acrosomal vesicle. Degradation of the zona pellucida by hydrolases and proteases released during the acrosomal reaction allows the sperm to begin entering the egg (3). Specific recognition proteins on the surfaces of egg and sperm facilitate fusion of their plasma membranes. Fusion and subsequent entry of the first sperm nucleus into the egg cytoplasm (4 and 5) trigger the release of Ca^{2+} within the oocyte. Cortical granules (orange) respond to the Ca^{2+} surge by fusing with the oocyte membrane and releasing enzymes that act on the zona pellucida to prevent binding of additional sperm. [Part (a) courtesy of Doug Kline. Part (b) adapted from L. Wolpert et al., 2001, *Principles of Development*, 2nd ed., Oxford Press, Figure 12-22.]

called ZP1, 2, and 3, the most interesting of which is ZP3 because it binds sperm. The sugar residues on ZP3 are needed for the sperm to recognize the oocyte; their removal prevents fertilization. The sugars on ZP3 are bound by beta-1,4-galactosyltransferase-I (GalT) on the surface of the sperm. When ZP3 on the egg induces aggregation of multiple copies of GalT on the head of one sperm, a G protein cascade in the sperm cell is triggered, resulting in exocytosis of the acrosome and release of its contents onto the surface of the egg (Figure 22-5b, steps **1** and **2**). This process commonly is called the *acrosomal reaction*. Sperm lacking GalT are unable to bind ZP3 or undergo the acrosomal reaction, although other proteins of the sperm surface allow GalT-deficient sperm to still bind to the zona pellucida. The recognition of ZP3 is species specific, thus preventing the formation of an inviable embryo with a sperm from one species and oocyte from another.

As the released acrosomal enzymes digest the zona pellucida, the sperm can penetrate this barrier to its entry. The plasma membranes of the sperm and egg then touch and fuse, allowing the sperm nucleus to enter the egg (Figure 22-5, steps **3–5**). Again, specific recognition proteins have been discovered that mediate membrane fusion, including CD9, an integrin in the egg plasma membrane, and Izumo, an immunoglobulin-domain protein in the sperm plasma membrane (Figure 22-6). Proteins such as Izumo and CD9 could become targets for controlling fertility.

Following mating of animals, sperm are in a race to approach and fuse with an egg. Under normal circumstances, many sperm cells are likely to reach each available egg. The first sperm to successfully penetrate the zona pellucida and fuse with an egg triggers a dramatic response by the egg that prevents *polyspermy*, the entry of other sperm that would bring in excess chromosomes. After the first sperm succeeds in fusing with the surface of the oocyte, a flux of Ca^{2+} flows through the oocyte at about 5–10 $\mu\text{m}/\text{sec}$, starting from the site of sperm entry. One effect of this Ca^{2+} flux is to cause vesicles located just under the plasma membrane of the egg, called cortical granules, to release their contents through the plasma membrane and form a shielding fertilization membrane that blocks other sperm from entering. In this *cortical reaction*, the movement of the granules is controlled by a rich assembly of actin microfilaments that forms from globular actin in response to sperm entry. The Ca^{2+} flux induced by sperm–egg fusion also acts as an effective signal for beginning development of the zygote. Among the earliest events to occur is completion of meiosis by the egg (recall that it is blocked in meiosis I, see Figure 22-3a). The haploid egg and sperm nuclei can then fuse, yielding the diploid nucleus of the zygote.

An oocyte contributes a considerable dowry to the newly formed zygote. In mammals and many other animal species, all the mitochondrial DNA in the zygote comes from the egg; no sperm mitochondrial DNA survives fertilization. Female-specific mitochondrial DNA inheritance has been used to trace maternal heritage in human history, for example following early humans from their origins in Africa. Little or no transcription occurs during oocyte meiosis and the first embryo cleavages, so during this time the oocyte's RNA is

▲ EXPERIMENTAL FIGURE 22-6 A sperm membrane protein mediates sperm–egg membrane fusion. Izumo, a protein in the plasma membrane of both mouse and human sperm, facilitates fusion between sperm and oocyte membranes. (a) Hamster eggs stripped of their zona pellucida were inseminated with heterozygous *Izumo*^{+/+} and homozygous *Izumo*^{-/-} mouse sperm. Phase-contrast micrographs show a single egg surrounded by multiple sperm. Six hours after insemination, Hoechst 33342, which stains sperm heads blue, was added to the medium. In the *Izumo*^{+/+} sperm, the white arrowheads indicate swelling sperm heads reacting with the egg after staining with Hoechst 33342. No fusion was observed with *Izumo*^{-/-} sperm. (b) In a second experiment, zona-free hamster eggs were inseminated with wild-type human sperm in the presence of anti-human Izumo (anti-hlzumo) or control IgG antibody. After 6 hours, the samples were stained with Hoechst 33342. Fusion was observed in the control sample (white arrowheads) but not in the presence of anti-hlzumo antibody. The inactivated sperm do not trigger a polyspermy block. [From N. Inoue et al., 2005, *Nature* **434**:234].

crucial. Among the most abundant are histone mRNAs that have short poly-A tails and as a result are translated inefficiently. Translation of these histone mRNAs is regulated by a stem-loop binding protein (SLBP) that binds to nucleotides in the 3' untranslated sequence. SLBP, regulated

by phosphorylation, cycles with the cell cycle so that histone mRNA is stabilized and translated preferentially during S phase. Other oocyte mRNAs are differentially activated during early embryonic development.

Genomic Imprinting Controls Gene Activation According to Maternal or Paternal Chromosome Origin

One might expect that the two pronuclei contributed by the sperm and oocyte would have equal capacity to activate genes, except for the difference between the X and Y chromosomes. Yet even after fertilization, when the paternally and maternally derived chromosomes are in the same nucleus, their male or female origin continues to have a lingering influence. This phenomenon has been revealed by experiments with mouse embryos. Diploid embryos can be constructed from two male pronuclei or two female pronuclei, which in theory should be adequate. However, zygotes with two male-derived haploid genomes form good extra-embryonic tissues but highly defective embryos. Conversely, zygotes with two female-derived haploid genomes form quite good embryos but poor yolk sacs and placentas, which are extra-embryonic tissues.

The explanation for these results is a process called **genomic imprinting**, which occurs during spermatogenesis and oogenesis. Imprinting is accomplished by modifications of the chromatin, but not the DNA sequence, in the developing gametes so that only certain genes are accessible for subsequent activation and transcription. In humans, for example, the gene for insulin-like growth factor 2 (*Igf2*) is present on both copies of chromosome 11 in the embryo, but is inactivated on the chromosome derived from the mother. Conversely, in some humans the *Igf-2r* gene on the male-derived chromosome 6 is inactive, whereas the female-derived allele is active. *Igf-2r* encodes a receptor for Igf-2, which transports Igf-2 to the lysosome for degradation. Imprinting does not alter the nucleotide sequence of DNA. For that reason either the maternal or paternal copy of every chromosome, if it ends up in a fertilized gamete, can function in development of progeny.

Abnormalities in gene imprinting that cause defects in growth, a variety of inherited diseases, and cancer, highlight the importance of this process. The mechanism of imprinting involves differential methylation of DNA during germ-line differentiation. The most common and important type of methylation alters CpG dinucleotides, which occur about 30 million times in the mammalian genome. Commonly 60–80 percent of the C residues in CpG dinucleotides are modified by several DNA methyltransferases. Most CpG methylations are erased in primordial germ-line cells during embryonic development, thus allowing reactivation of imprinted genes. Subsequent re-methylation as germ-line cells develop differentially affects some genes depending on whether a chromosome is going through oogenesis or spermatogenesis (i.e., whether the animal is male or female). Thus eggs and sperm end up with different, distinct imprints. After fertilization, a second

wave of demethylation occurs in cleavage and blastocyst-stage mouse embryos, though this does not affect imprinted genes.

The reason imprinting has evolved is unclear. Relatively few genes, about eighty in mammals, are known to be imprinted. However, the genes regulated in this manner play a role in controlling embryonic growth and development. This observation suggests a possible relation between growth control and the maternal or paternal origin of the genes.

Too Much of a Good Thing: The X Chromosome Is Regulated by Dosage Compensation

Males have one X chromosome and females have two. Because of this difference in the number of X chromosomes in the two sexes, a female embryo potentially will make twice as much of each of the products encoded by X-chromosome genes as a male does. That double-dose turns out to be toxic, and a variety of mechanisms have evolved in many species, including humans, to restore a viable balance of sex-chromosome gene expression.

About four days after fertilization, mammalian embryos consist of an outer sheath of cells, which will become extra-embryonic tissue such as the placenta, and an inner mass of cells, which will form the embryo proper. At this stage, one of the two X chromosomes (either X_m from the maternal parent or X_p from the paternal parent) in each of the inner cells of a female embryo becomes highly condensed and transcriptionally inactive. Half the cells are left with an active X_p chromosome; the other half, with an active X_m chromosome. X inactivation is a mechanism of *dosage compensation* that ensures that males and females produce roughly similar levels of X-chromosome gene products. Once an embryonic cell undergoes X inactivation, the same X chromosome (X_m or X_p) remains active and the other remains inactive in all the descendants of that cell. Thus all women are, in this sense, genetic mosaics, since half their cells have an active X_m and half have an active X_p . Because the two X chromosomes differ on average at 1 in 1000 base pairs, the cells in females will no longer be identical with respect to active X-linked genes. Males, in contrast, have the same active X chromosome in every cell.

Mammalian dosage compensation requires a region of the X chromosome called the X-inactivation center (Figure 22-7a). Within this region are two genes, *Xist* and *Tsix*, that both encode long RNAs. Because the genes overlap and are transcribed in opposite directions, their RNA products are antisense with respect to each other (hence the reversed names). *Xist* RNA, which is made from only one of the two X chromosomes in a female cell, actually coats the chromosome from which it is made. Since *Xist* RNA does not move to the other X chromosome, that X is not coated and as a result remains active.

The mechanism for triggering expression of the *Xist* gene from only one chromosome is incompletely understood. Cis-acting control elements in the X-inactivation center appear to detect the presence of the two X chromosomes in female cells (Figure 22-7b). A clue about the sensing process comes from the observation that the two X-inactivation centers in a female

▲ FIGURE 22-7 Dosage compensation in mammalian females.

Early in embryogenesis, one of the female X chromosomes becomes highly compacted in a special chromatin structure; this compacted, transcriptionally inactive chromosome is called a Barr body. The mechanism that detects the presence of two X chromosomes in the female embryo involves a region on the X chromosome, the X-inactivation center (XIC), diagrammed in (a). The transient pairing of the XICs on the maternal and paternal X chromosomes in females initiates the process of dosage compensation, outlined in (b). Since pairing and subsequent events occur randomly in each cell, half the cells will have the maternally derived X inactivated and the other half will have the paternally derived X inactivated. Since male embryos have only one X chromosome no XIC pairing can occur and no *Xist* RNA is produced, hence there is no X-chromosome inactivation.

cell transiently co-localize prior to one of the X chromosomes becoming inactive. This co-localization may result in (1) low expression of *Tsix* from the chromosome that will be inactivated, which leads to (2) a temporary chromatin-regulated silencing of *Xist* transcription, followed by (3) a surge of high *Xist* expression leading to inactivation of the chromosome.

After production of *Xist* RNA, Polycomb-group proteins modify lysine 27 residues on histone H3 tails of the *Xist*-

coated X chromosome. This and other early changes trigger a series of chromatin modifications that lead to compaction and transcriptional inactivity.

KEY CONCEPTS OF SECTION 22.2

Gametogenesis and Fertilization

- Early in mammalian embryogenesis, the primordial germ cells migrate to the gonads and begin, but do not complete, the production of gametes (oocytes or sperm) in utero.
- In mammalian oogenesis, primary oocytes arrested in meiosis form in the embryo and are stored in the ovary; they complete meiosis, forming haploid mature oocytes (eggs), following fertilization (see Figure 22-3a). Oocytes contain a pool of mitochondria, mRNAs, and other materials necessary for early development.
- In mammalian spermatogenesis, germ-line precursors form in the embryo and are stored in the testis; these diploid cells undergo meiosis after birth, forming haploid spermatids (see Figure 22-3b). Differentiation of spermatids (spermiogenesis) yields mature sperm, elongated cells with a long flagella and compressed nucleus.
- During fertilization, sperm initially recognize and bind to the gelatinous layer (zona pellucida) on the outside of the oocyte. This interaction, which involves glycoproteins (e.g., ZP3) in the zona pellucida and proteins on the sperm surface, triggers the acrosomal reaction in the sperm. Enzymes released from the sperm acrosome degrade the zona pellucida, leading to fusion of the sperm and egg plasma membranes (see Figure 22-5).

■ Fertilization must be restricted to a single sperm to prevent chromosome imbalances. Sperm-egg fusion induces changes in the oocyte that exclude entry of other sperm.

■ Although the sperm and oocyte each contribute a haploid genome, genomic imprinting restricts which alleles are active in each cell. In the case of some imprinted genes, the paternal copy is active in the embryo and the corresponding maternal copy is inactive, or vice versa.

■ Males survive with one X chromosome, but the two X chromosomes in females could lead to a double dose of X-gene products that is harmful. This situation is avoided in human females by inactivation of one of the two X chromosomes in every cell of an early embryo, a process called dosage compensation (see Figure 22-7).

22.3 Cell Diversity and Patterning in Early Vertebrate Embryos

Fertilization produces a single cell, the zygote, which divides rapidly. Within a few days, the newly formed cells start sending and receiving various signals that largely determine their future fates. The first distinctions to appear are two different

▲ **FIGURE 22-8 Cleavage divisions in the mouse embryo.** There is little cell growth during these divisions, so that the cells become

progressively smaller. See text for discussion. [Copyright Oxford University Press, T. Fleming.]

cell types and then the initial polarization of the embryo along its various axes. In time, further distinctions lead to formation of multiple cell layers from which tissues and organs begin to form. Much of this early fate determination requires signaling systems that we discussed in Chapters 15 and 16. The general theme is that a few cells will begin to produce a signal, and other cells will produce the receptors that make them responsive to that signal; signal reception then induces the production of certain transcription factors that regulate batteries of genes to control the fate of the receiving cell.

Cleavage Leads to the First Differentiation Events

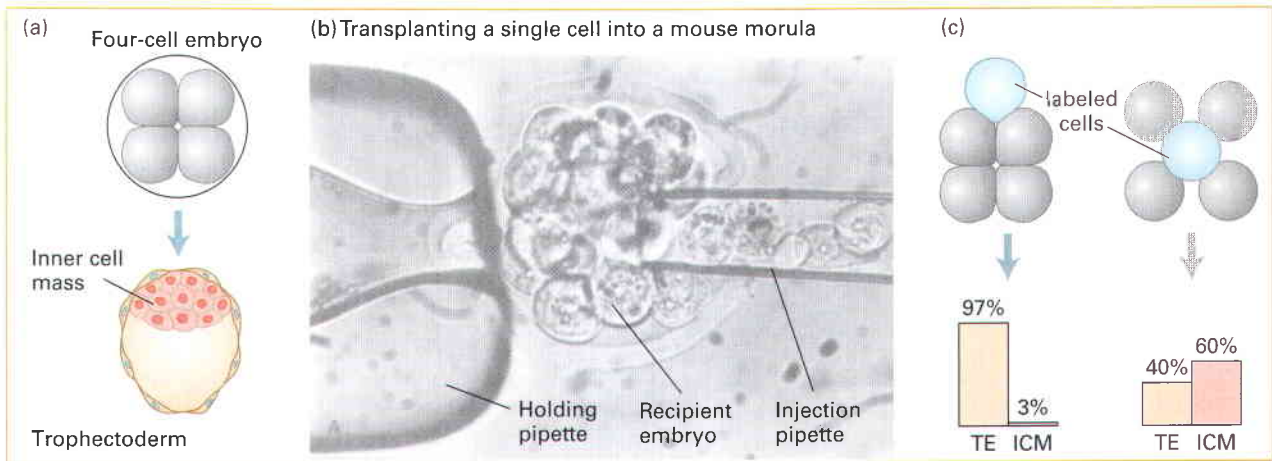

The zygote is the ultimate *totipotent* cell because it has the capability to generate all the cell types of the body. Fertilization is quickly followed by cleavage, cell divisions that take about one day each in the mouse. In mammals, cleavage divisions occur before the embryo is implanted in the uterus wall (see Figure 22-1). The condensed, transcriptionally inactive chromatin from the sperm returns to a more normal state by replacement of the sperm's special histones with normal histones provided by the oocyte.

Initially the cells are fairly spherical and loosely attached to each other (Figure 22-8). As demonstrated experimentally in sheep, each cell at the eight-cell stage has the potential to give rise to a complete animal. Three days after fertilization the 8-cell embryo divides again to form the 16-cell *morula* (from the Greek for “raspberry”), after which the cell affinities increase substantially and the embryo undergoes *compaction*, a process that depends in part upon the surface molecule E-cadherin (Chapter 19). Compaction is driven by increased cell–cell adhesion and initially results in a more solid mass of cells, the compacted morula. Next, some cell–cell adhesions diminish, and fluid begins to flow into an internal cavity, the *blastocoel*. Additional divisions produce a **blastocyst**-stage embryo, composed of ≈64 cells that have separated into two cell types: *trophoblast* (*TE*), which will form extra-embryonic tissues like the placenta, and the *inner cell mass* (*ICM*), which gives rise to the embryo proper.

Whether a cell assumes a TE or ICM fate is determined by its location within very early embryos. This can be demonstrated experimentally by placing a labeled cell on the outside or the inside of a very early embryo (Figure 22-9). Labeled cells placed on the outside form extra-embryonic tissues (TE fate) almost exclusively, and those inserted inside preferentially form embryo tissues (ICM fate). DNA microarray analysis of gene expression at each stage of early development reveal dramatic changes in which genes are expressed as the embryo progresses from the 2-cell to blastocyst stage. Even these very early embryos use Wnt, Notch, and TGFβ signaling pathways (Chapter 16).

Both ICM and TE cells have the properties of stem cells: That is, each type can divide to renew itself and to start its own distinct lineage that produces diverse populations of differentiated cells. The inner cell mass is the source of **embryonic stem (ES) cells**, which can contribute to any part of the embryo (see Figure 21-7). The isolation of these cells as cell lines has enabled dramatic advances in mouse genetic manipulations. The earliest known sign of the ICM fate is expression of the *Oct4* gene, which is a critical regulator for maintaining cells in a plastic *pluripotent* state.

As shown in Figure 22-9a, ICM cells are located on one side of the blastocoel, while TE cells form a hollow ball around the inner cell mass and blastocoel. At this blastocyst stage, the TE cells are in an organized epithelial sheet, with cell–cell junctions between adjacent cells. In contrast, the ICM cells are a loose mass that can be described as *mesenchyme*, a term commonly applied to loosely organized and loosely attached cells. During development, cells often undergo an *epithelial-mesenchymal transition*, or the reverse. Epithelial cells form sheets that act as a barrier, move in harmony, and have a clear polar character from one side of the sheet to the other. Mesenchymal cells are bold individuals, less responsive to peer pressure. With their ability to cut loose from each other, they can migrate as individual cells, seed new organs, form circulating blood cells, and adhere in a three-dimensional mass, such as the inner cell mass.

▲ EXPERIMENTAL FIGURE 22-9 Cell location determines cell fate in the early embryo. (a) A 4-cell embryo normally develops into a blastocyst consisting of trophoblast (TE) cells on the outside and inner cell mass (ICM) cells inside. (b) In order to discover whether position affects the fates of cells, transplantation experiments were done with mouse embryos. First, recipient morula-stage embryos had cells removed to make room for implanted cells. Then donor morula-stage embryos were soaked in a dye that does not transfer between cells. Finally, labeled cells from the donor embryos were injected into inner or outer regions of the recipient embryos, as shown in the

micrograph. The recipient embryo is held in place by a slight vacuum applied to the holding pipette. (c) The subsequent fates of the descendants of the transplanted labeled cells were monitored. For simplicity, 4-cell recipient cells are depicted, although morula-stage (16-cell) embryos were used as both donors and recipients. The results, summarized in the graphs, show that outer cells overwhelmingly form trophoblast and inner cells tend to become inner cell mass but also form considerable trophoblast. [Parts (a) and (c) adapted from L. Wolpert et al., 2001, *Principles of Development*, 2nd ed., Oxford Press, Figure 3-12. Part (b) from R. L. Gardner and J. Nichols, 1991, *Human Reprod.* **6**:25–35.]

The Genomes of Most Somatic Cells Are Complete

What is happening to the genome during early embryonic stages? Although different parts of the genome are transcribed in different cells, the genome itself is thought to be identical in nearly all cells. One well-documented exception occurs during development of lymphocytes from hematopoietic precursors. Segments of the genome are rearranged or lost during lymphocyte development, generating clones of lymphocytes whose genomes are unique (Chapter 24). Also, mature erythrocytes (red blood cells) lack a nucleus and thus have no nuclear genome. Most somatic cells, however, appear to have an intact genome, equivalent to that in the germ line.

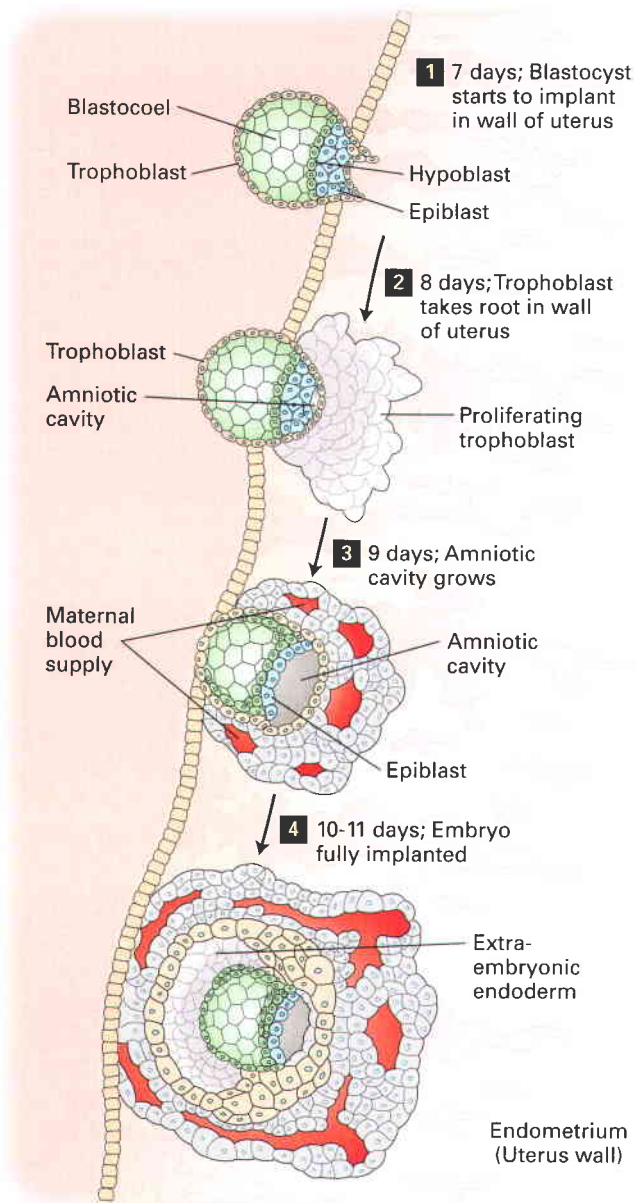

Evidence that at least some somatic cells have a complete and functional genome comes from the successful production of cloned animals by nuclear-transfer cloning. In this procedure, the nucleus of an adult (somatic) cell is introduced into an egg that lacks its nucleus; the manipulated egg, which contains the diploid number of chromosomes and is equivalent to a zygote, then is implanted into a foster mother. The only source of genetic information to guide development of the embryo is the nuclear genome from the donor somatic cell. The frequent failure of such cloning experiments raises questions about how many adult somatic cells do in fact have a complete functional genome. Even the successes, like the famous cloned sheep “Dolly,” have some medical problems. Even if differentiated cells have a physically complete genome, clearly only portions of it are tran-

scriptionally active (Chapters 6 and 7). A cell could, for example, have an intact genome, but be unable to properly reactivate it due to inherited chromatin states.

Further evidence that the genome of a differentiated cell can revert to having the full developmental potential characteristic of an embryonic stem cell comes from experiments in which differentiated olfactory sensory neurons were genetically marked with green fluorescence protein (GFP) and then used as donors of nuclei. When the nuclei from differentiated olfactory cells were implanted into enucleated mouse oocytes, 14 percent of the oocytes developed into blastocysts that produced GFP. These GFP-marked blastocysts were used to derive embryonic stem (ES) cell lines, which were then used to generate mouse embryos. After implantation into female mice, these embryos, derived entirely from olfactory neuron genomes, formed healthy mice. Thus the genome of a differentiated cell can be reprogrammed completely to form all tissues of a mouse.

Gastrulation Creates Multiple Tissue Layers, Which Become Polarized

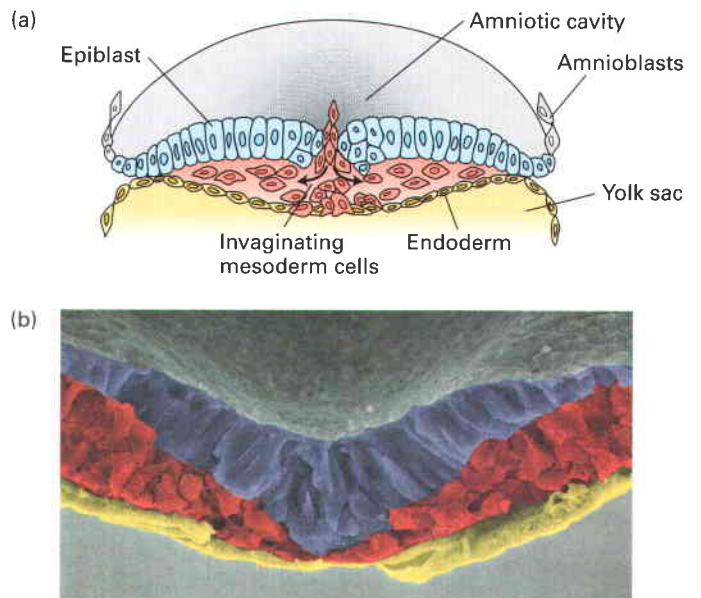

The embryonic cells composing the inner cell mass of the blastocyst have impressive abilities, but they hardly look like an embryo. Soon after the blastocyst implants into the uterine wall, the loose-knit conglomeration of ICM cells is turned into a multi-layered structure with head-tail, front-back, and

◀ **FIGURE 22-10 Human development from days 7 to 11 after fertilization.** Implantation of the blastocyst into the wall of the uterus occurs at about 7 days (see Figure 22-1 for earlier stages). The blastocyst is polarized in that the inner cell mass (ICM) is at one end and the blastocoel (fluid-filled cavity) at the other, both encased in trophoblast cells, which are now known as the trophoblast. By day 7 (1), the ICM cells of the blastocyst have already begun to separate into two layers—the hypoblast (green) and the epiblast (blue). The epiblast will form the embryo proper and the hypoblast will form extra-embryonic structures (in addition to those formed by trophoblast). Next, the trophoblast cells proliferate and invade the wall of the uterus (2), which is necessary for the embryo to start receiving nourishment from the mother. By day 9 (3), the amniotic cavity (gray), which forms between the epiblast and the trophoblast, is enlarging. By 10–11 days (4), the embryo (now the size of a period on this page) is fully implanted and is being supplied by the maternal circulatory system. The extra-embryonic endoderm (white) is derived from the hypoblast and will form the yolk sac, a remnant of our evolutionary history when our ancestors required significant amounts of yolk to nourish the embryo. The two cell layers of the implanted embryo are transformed into the three germ layers during the next stage, gastrulation. [Adapted from S. F. Gilbert, 2006, *Developmental Biology*, 8th ed., Sinauer Press, Figure 11-33.]

left-right polarity. As depicted in Figure 22-10, the inner cell mass initially separates into two layers called the *hypoblast* and the *epiblast*. The epiblast will form the embryo proper. The hypoblast will form extra-embryonic structures that connect to the mother's circulation. Other extra-embryonic structures will form from the trophoblast, called the *trophoblast* after implantation.

In the mouse, in which axis formation has been studied extensively, the first sign of the anterior-posterior axis becomes apparent at 6.5 days (2 weeks in humans). At this time a visible groove, the *primitive streak*, forms on the surface of the epiblast in the region that will become the posterior of the embryo. Along the primitive streak, cells leave the epiblast layer and move into the space between the epiblast and hypoblast in the process of gastrulation (Figure 22-11). The first cells to invaginate form embryonic **endoderm**;

▲ **FIGURE 22-11 Gastrulation in animals.** During gastrulation, epiblast cells migrate to create the three germ layers: ectoderm, mesoderm, and endoderm. Cells in the different layers have largely distinct fates and therefore represent distinct cell lineages. (a) Shown here is a sketch of a human embryo about 16 days after fertilization of an egg. The first cells to move from the epiblast into the interior form endoderm. They displace the hypoblast (not shown) and appear as a layer along the bottom of the interior space. The next cells to invaginate become mesoderm. The remaining epiblast cells become ectoderm. (b) Scanning electron micrograph of a cross section of a similar-stage embryo. [Part (a) adapted from N. A. Campbell and J. B. Reece, 2005, *Biology*, 7th ed., Pearson/Benjamin Cummings, Figure 47.13. Part (b) courtesy of Kathy Sulik, University of North Carolina–Chapel Hill.]

later arrivals become **mesoderm**. Cells that do not invaginate to become endoderm or mesoderm remain behind in the epiblast to become **ectoderm**. The post-gastrulation embryo proper thus has three germ layers and is polarized along the dorsal-ventral axis and the anterior-posterior axis. The ectoderm will make neural and epidermal cells; the mesoderm will make muscle, connective tissue, and blood; the endoderm will make gut epithelia.

Once the three germ layers are established, they subsequently divide into cell populations with different fates. There appears to be a progressive restriction in the range of cell types that can be formed from stem cells and precursor cells as development proceeds. An early embryonic stem cell, as we've seen, can form every type of cell; an ectodermal cell has a choice between neural and epidermal fates; a keratinocyte precursor can form skin but not neurons. These observations raise two important questions: How are cell fates progressively restricted during development? Are these restrictions irreversible? Such questions are often addressed with transplant experiments, asking what a cell will do when moved to an abnormal position in an embryo. Will it retain the fate of the old location, or adopt a fate appropriate to the new location? In addressing such questions, it is important to remember that what a cell in its normal *in vivo* location will do may differ from what a cell is capable of doing if it is manipulated experimentally. Thus the observed limits to what a cell can do may result from natural regulatory mechanisms or may reflect a failure to find conditions that reveal the cell's full potential.

The fates of different parts of the early embryo were determined in the early days of embryology by marking amphibian or chick embryo cells with ink and tracking them. More recently, chimeric animals composed of chicken and quail cells have been used to study cell-fate determination during embryonic development. Embryos composed of cells from both bird species develop fairly normally, yet the cells derived from each donor are distinguishable under the microscope. Thus the contributions of the different donor cells to the final bird can be ascertained. In addition to testing which cells can form which types of tissue, the rigidity of cell-fate determination can be tested. When cells from one germ layer are transplanted into one of the other layers, they do *not* give rise to cells appropriate to their new location. Thus the endoderm, mesoderm, and ectoderm are not only morphologically distinct; they are firmly determined as different cell types with different fates.

In vertebrates, secreted protein signals are involved in directing not only the initial formation of the germ layers but also their polarization along the body axis. In the remainder of Section 22.3, we examine the role of secreted signals and their antagonists in early development.

Signal Gradients May Induce Different Cell Fates

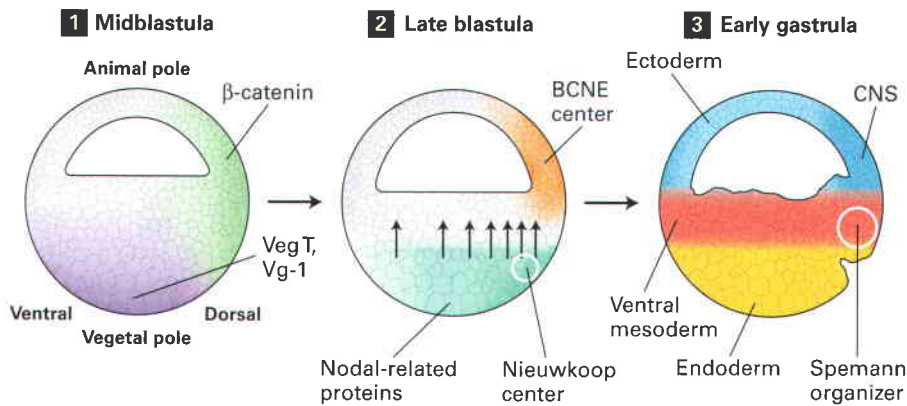

The most intensive and revealing studies of gastrulation and formation of the initial tissues have been done in the clawed toad *Xenopus laevis* (more commonly described as a frog). By dissecting and transplanting *Xenopus* tissues, developmental biologists have identified powerful signals that direct cell fates in the early embryo. Some of these signals have

been found to function in similar ways in early mammalian embryos.

The *Xenopus* egg is huge, about 1 mm in diameter. After fertilization, this giant cell divides, initially without growth, to make successively smaller cells that vary in size. Once the embryo is a ball of cells, a blastocoel cavity opens within the ball. The cells at one end of the embryo are large; this side of the embryo is called the *vegetal pole*. Cells at the opposite end are smaller; this side is known as the *animal pole*. Morphological and molecular markers clearly reveal the polarization of the embryo by the midblastula stage. For example, the proteins VegT and Vg-1 are molecular markers for the vegetal pole. On what will become the dorsal side ("back") of the embryo, the protein β -catenin accumulates to high levels. The position of β -catenin accumulation is controlled by the site of sperm entry. As we have seen in Chapter 16, β -catenin is activated as a transcription factor by Wnt signals (see Figure 16-32). Even in the absence of a Wnt signal, accumulated β -catenin can trigger the induction of specific genes.

The accumulation of β -catenin is the earliest known indicator of the frog dorsal-ventral axis. More importantly, β -catenin is essential for the formation of two signal-emitting centers on the dorsal side of the late blastula: the *Nieuwkoop center* and the *BCNE* (*blastula chordin and noggin expression*) center (Figure 22-12). The Nieuwkoop center forms where VegT, Vg-1, and high levels of β -catenin overlap, that is, in the vegetal part of the dorsal side. Some of the future endoderm is located in this same region. The Nieuwkoop center releases Nodal proteins, which are members of the transforming growth factor β (TGF β) family of secreted protein signals (Chapter 16). The BCNE center, which forms where future neural-ectoderm cells arise, is detectable through its expression of genes encoding some transcription factors as well as Chordin and Noggin. These two secreted proteins are antagonists of bone morphogenetic proteins (BMPs), other members of the TGF β family. Thus the BCNE center seems to be mainly involved in preventing BMP action. At the equator of the slightly later, gastrula-stage embryo, a central belt of cells that forms between the ectoderm at the animal pole and the endoderm at the vegetal pole becomes the mesoderm. During *Xenopus* gastrulation, the cells forming the future endoderm and mesoderm invaginate by the same sort of process that occurs in mammalian embryos (see Figure 22-11).

We know now that the mesoderm is induced by signals, particularly TGF β signaling proteins. In the search for mesoderm-inducing factors, researchers added everything but the kitchen sink to early frog embryos. A remarkable range of molecules was found to induce mesoderm cells, including many that could not possibly be natural inducers. For a molecule to be considered a genuine, natural inducer, it has to meet three criteria: (1) the molecule has to be necessary for mesoderm induction to occur (based on interference or mutants); (2) it has to be sufficient to induce mesoderm from cells not normally fated to be mesoderm (based on ectopic expression tests, that is, expression in abnormal sites); and (3) it has to be produced at the right time and place in a normal embryo (based on antibody staining or *in situ* hybridization). Few

▲ FIGURE 22-12 Signaling centers in the early *Xenopus* embryo. Cross-sections of the embryo at three stages are shown. The three germ layers—endoderm (yellow), mesoderm (red), and ectoderm (blue)—are determined by the gastrula stage (3). They derive from earlier embryos (1 and 2), which are polarized by VegT (a transcription factor) and Vg-1 (a TGF β signal) to form the animal

pole and by Nodal signals from the Nieuwkoop center to form ventral-to-dorsal cells. Mesoderm is induced by signals coming from the vegetal region to the central embryo. Dorsal-ventral cell fates are also controlled by signals from the Spemann organizer in the gastrula. See text for further discussion. [Adapted from L. Wolpert et al., 2001, *Principles of Development*, 2nd ed., Oxford Press, Figure 3-35.]

molecules fit all these requirements, but some TGF β proteins do.

In some cases, the induction of cell fates involves a binary choice: In the presence of a signal, the cell is directed down one developmental pathway; in the absence of the signal, the cell assumes a different developmental fate or fails to develop at all. Such signals can work in a *relay mode*. That is, an initial signal induces a cascade of induction in which cells close to the signal source are induced to assume specific fates; they, in turn, produce other signals to organize their neighbors (Figure 22-13a). Alternatively, a signal may induce different cell fates, depending on its concentration. In this *gradient mode*, the fate of a receiving cell is determined by the amount of the signal that reaches it,

which is related to its distance from the signal source (Figure 22-13b). Any substance that can induce different responses depending on its concentration is often referred to as a **morphogen**.

The concentration at which a signal induces a specific cellular response is called a *threshold*. A graded signal, or morphogen, exhibits several thresholds, each one corresponding to a specific response in receiving cells. For instance, a low concentration of an inductive signal causes a cell to assume fate A, but a higher signal concentration causes the cell to assume fate B. In the gradient mode of signaling, the signal is newly created, and so it has not built up to equal levels everywhere. Alternatively, the signal could be produced at one end of a field of cells and destroyed or inactivated at the other (the “source and sink” idea), so a graded distribution is maintained.

Studies with activin, a TGF β -type signaling protein that can alter cell fate in early *Xenopus* embryos, have provided insight into how cells determine the concentration of a graded inductive signal. Activin helps organize the mesoderm along the dorsal-ventral axis of an animal. Specific genes are used as indicators of the tissue-creating effects of signals such as activin. For instance, a low concentration of activin induces expression of the *Xenopus brachyury* (*Xbra*) gene throughout the early mesoderm. Higher concentrations of activin induce expression of the *Xenopus goosecoid* (*Xgsc*) gene. *Xgsc* protein is able to transform ventral into dorsal mesoderm; so the local induction of *Xgsc* by activin causes the formation of dorsal, rather than ventral, mesodermal cells near the activin source.

Using ^{35}S -labeled activin, scientists demonstrated that *Xenopus* blastula cells each produce some 5000 type II TGF β -like receptors that bind activin. Findings from additional experiments showed that maximal *Xbra* expression was achieved when about 100 receptors were occupied. At a

▲ FIGURE 22-13 Two modes of inductive signaling. In the relay mode (a), a short-range signal (red arrow) stimulates the receiving cell to send another signal (purple), and so on for one or more rounds. In the gradient mode (b), a signal produced in localized source cells (pink cells) reaches nearby cells in larger amounts than the amounts reaching distant cells. If the receiving cells respond differently to different concentrations of the signal (indicated by width of the arrows), then a single signal may create multiple cell types.

concentration of activin at which 300 receptors were occupied, cells began expressing higher levels of *Xgsc*. Similar results were obtained with blastula cells experimentally manipulated to produce sevenfold higher levels of the activin type II receptor. These findings indicate that blastula cells measure the absolute number of ligand-bound receptors rather than the ratio of bound to unbound receptors, and confirm the importance of signal concentration.

Signal Antagonists Influence Cell Fates and Tissue Induction

The most dorsal of the mesoderm cells in the early frog gastrula become a famous signaling center called the **Spemann organizer** (Figure 22-12, **3**). This organizer, reported by Spemann and Mangold in 1924, can be transplanted into a host embryo, where it takes over part of the host embryo and causes the formation of a nearly complete new axis (Figure 22-14). The Spemann organizer is formed under the influence of Nodal and perhaps other signals from the Nieuwkoop center.

The Spemann organizer is the source of a remarkable number of secreted signal antagonists. These include Chordin and Noggin (BMP antagonists); Frzb-1, Crescent, sFRP2, and Dkk-1 (Wnt antagonists); and the multi-signal antagonist Cerberus, which dampens the effects of Wnt and BMP and Nodal signals. When Noggin is applied to embryos that lack a functional Spemann organizer, the embryos develop normally. This finding shows that Noggin all by itself can mimic the effect of the Spemann organizer. A ventral signaling center, at the opposite end of the mesoderm from the Spemann organizer, makes several signals including BMP4 (a TGF β family signal). Thus the

two signaling centers, one dorsal and one ventral, appear to battle each other for control of cell fates across the mesoderm.

You have undoubtedly noticed that many of the molecules involved in tissue formation in early embryos are signal antagonists. One effect of such an antagonist can be to sharpen or move a boundary between cell types. A signal coming from source cells is progressively less potent with distance; at some point, it falls below a threshold amount and is without effect. If a secreted antagonist comes from the opposite direction, it will block the action of the signal even in cells receiving above-threshold amounts.

We see an example of this phenomenon in the formation of neural cells in the anterior of frog embryos. Normally, secreted TGF β proteins *prevent* the formation of neural cells near the animal pole of *Xenopus* embryo. When the animal pole is removed and placed into culture, it is called the “animal cap.” Production of BMP4 (a TGF β family signal; see Chapter 16) by an animal cap prevents formation of neural tissue in the culture. The effect of signals and other regulators on neural induction can be tested by exposing parts of the animal cap from *Xenopus* embryos to individual proteins and seeing whether neural cells form. This type of *in vitro* experiment first revealed the ability of Chordin to antagonize BMP4 and induce neural-cell identity. Only when BMP signaling is successful can non-neural cell types form. Together, these data led to a simple model in which Chordin prevents BMP4 from binding to its receptor. In principle, inhibition could occur by the direct binding of Chordin to BMP receptors or to BMP molecules themselves. Biochemical studies demonstrated that Chordin binds BMP2 and BMP4 homodimers or BMP4/BMP7 heterodimers with high affinity ($K_d = 3 \times 10^{-10}$ M) and prevents them from binding to their receptors (Figure 22-15). Chordin-mediated inhibition of BMP signaling is relieved by Xolloid protein, a protease that specifically cleaves Chordin in Chordin–BMP complexes, releasing active BMP.

Cerberus, another antagonist secreted from cells in the Spemann organizer, is named after the mythological guardian dog with three heads because it has binding sites for three different types of powerful signals—Wnt, Nodal, and BMP. The binding of these signals by Cerberus prevents activation of their respective receptors. By inactivating Wnt, Nodal, and BMP signals having roles in the development of the trunk and tail of the body, Cerberus promotes head development.

In *Xenopus*, neural induction seems to be the default state that must be actively blocked in order for other cell types to develop. In chicks and mammals, however, fibroblast growth factor (FGF), BMPs, and Wnt appear to be necessary signals for induction of neural tissue in the posterior embryo. In the anterior, the actions of BMP and Wnt are prevented by antagonists (Figure 22-16). These antagonists are produced in a region called the *node*, which is functionally equivalent to the Spemann organizer in frogs. The node is a depression at the anterior end of the primitive streak; during gastrulation, the streak with the node leading it gradually expands forward toward the head.

▲ EXPERIMENTAL FIGURE 22-14 A transplanted Spemann organizer directs formation of a new body axis in host embryo. (Top) Normal frog embryo at swimming tadpole stage. (Bottom) When the Spemann organizer, a powerful signaling center, is transplanted into an early host embryo so that it now has two organizers (right, the implant is the white patch at the bottom), much of the main neural and mesodermal axis is duplicated (left). See text for discussion. [From E. de Robertis and H. Kuroda, 2004, *Ann. Rev. Cell Devel. Biol.* **20**:285].

▲ FIGURE 22-15 Modulation of BMP4 signaling in *Xenopus* by Chordin and Xolloid. (a) Chordin binds BMP4, a TGF β -family secreted protein signal, and prevents it from binding to its receptor. See Figure 16-4 to review the TGF β signaling pathway. (b) Xolloid

specifically cleaves Chordin in the Chordin–BMP4 complex, releasing BMP4 in a form that can bind to its receptor and trigger signaling. [See S. Piccolo et al., 1997, *Cell* **91**:407].

Sorting out all the signals and antagonists involved in determining cell fates along the three body axes will require much additional research. Nonetheless, biologists now have identified most of the powerful regulators that cause the formation of different tissue types in the early embryo, including those that control differences between the left and right sides of the body.

A Cascade of Signals Distinguishes Left from Right

Having discussed dorsal-ventral and anterior-posterior axis formation, we turn next to the genetic controls that organize

the left-right axis. Antibody staining and in situ hybridization have been used to look at gene expression in late gastrula embryos. One of the most striking and interesting findings has been that some genes are active on only the left or only the right side of the embryo. These include genes encoding three secreted protein signals: Sonic hedgehog, FGF, and Nodal (Figure 22-17). Experiments in which genes with this type of expression pattern were disrupted have shown that such genes are not merely responding to left-right information; they are part of the system for controlling the subsequent pattern of the embryo. An animal tissue or organ may exhibit left-right asymmetry in two ways: by forming primarily on one side of the body or by having an asymmetric

◀ FIGURE 22-16 Regulators of anterior-posterior cell fates in the mouse embryo. The late gastrula embryo, which is actually curled, is depicted here as a flattened oval with three layers, ectoderm, mesoderm, and endoderm. The primitive streak, where future mesoderm cells moved inside during gastrulation, is indicated as a purple area on the surface of the oval. The node (green circle) is a signaling center that forms earlier and eventually becomes the notochord (see Figure 22-39). Regulatory signals that control anterior-posterior patterning are indicated above the oval. Wnt, BMP, and FGF secreted signaling proteins are made by posterior tissues and direct cells to assume posterior-cell fates such as neural tissue. The actions of BMP and Wnt proteins are blocked in the anterior embryo by antagonistic proteins that are made by cells in the node and accumulate there. [Adapted from S.F. Gilbert, 2006, *Developmental Biology*, 8th ed., Sinauer Press, Figure 11-41.]

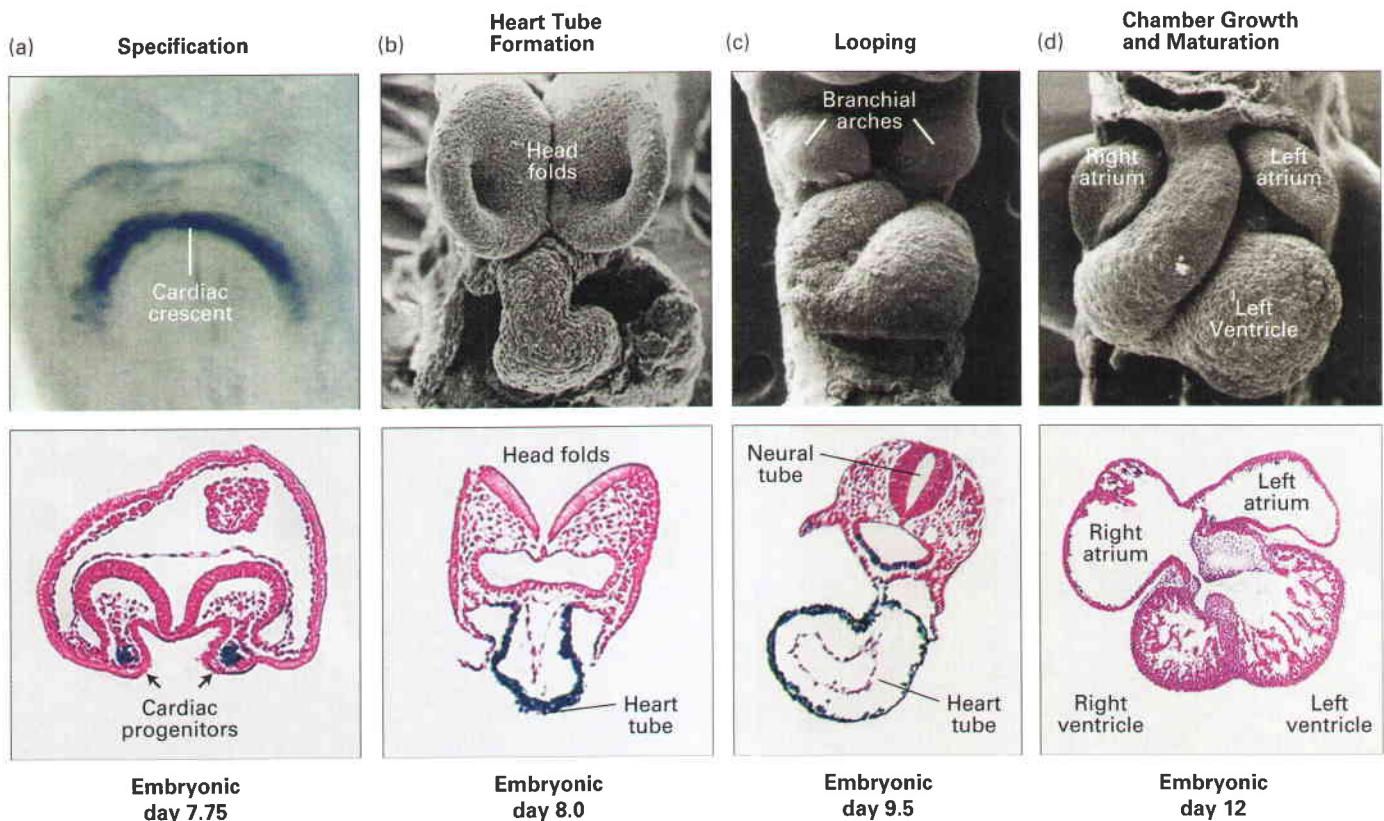

▲ **EXPERIMENTAL FIGURE 22-17** Nodal protein is produced only on side of a 8-day mouse embryo. In this in situ hybridization experiment, the embryo was permeabilized and then incubated with a probe specific for *nodal* mRNA. The probe was made with nucleotide analogs that can be bound by antibodies. After hybridization, the specimen was exposed to an anti-probe antibody that is covalently linked to a reporter enzyme. After addition of the enzyme substrate, a colored precipitate formed where the probe hybridized to the nodal mRNA, obviously on one side only. This type of hybridization experiment is widely used in studying gene expression in embryos. Other experiments showed that the Nodal-producing side eventually forms left-side structures. [From H. Hamada et al., 2002, *Nature Genet.* 3:103].

morphology. To see how left-right asymmetry can be created during development, we consider the heart, which is asymmetric in both ways.

The normal process of heart development in the mouse is shown in Figure 22-18. The most amazing feature of the heart is that a tiny organ formed early in embryogenesis begins beating at 23 days (human), when the entire embryo is about 2.5 mm long, and continues its reliable pumping as it grows to about $6 \times 8 \times 12$ cm and weighs about a third of a kilogram. This is like growing an outboard motor into the huge engine of an ocean liner, while all the time keeping the motor running!

At the earliest stages of heart development, the *Nkx2.5* gene, a member of a family of *Nkx* genes that encode homeodomain transcription factors, is expressed in heart precursor cells in the lateral plate mesoderm. The first *Nkx2.5*-type gene was discovered as a *Drosophila* mutant by virtue of its phenotype: no heart. The fly mutant was named *tinman* after the Wizard of Oz character, who thought he had no heart. Humans with only one copy of *Nkx2.5* have a variety of heart defects. The identification of *Nkx2.5* allowed researchers to detect early heart precursor cells that express

▲ **FIGURE 22-18** Heart development in the mouse embryo from day 7.75 to day 12. Whole mount and scanning electron micrographs are shown at top; transverse histological sections, at the bottom. In situ hybridization was used to detect the heart primordial structures (blue) in whole mount and sections. (a) The cardiac crescent, the earliest heart primordium formed, is detectable by day 7.75. (b) The heart tube develops from the cardiac crescent underneath the head folds. (c) The heart tube begins looping

beneath the branchial arches. (d) Chamber growth and maturation generates the four chambers of the heart by day 12. The blue stains in the tissue sections reveal proteins made under the control of key heart regulatory genes, including *Nkx2.5* (see text). Such regulatory genes are important for understanding cell-fate determination mechanisms and also serve, as shown here, as superb markers of early precursor cells that could not be recognized otherwise. [From E. N. Olson and M. D. Schneider, 2003, *Genes & Devel.* 17:1937.]

the gene, cells that had not been distinguishable from other embryonic cells prior to having this powerful new marker gene (see Figure 22-18). Subsequent experiments using this marker gene have been designed to identify factors that control the earliest steps in heart formation. Similar discoveries of early regulators for other organs and tissues are providing tools for discovering what signals control their formation. The *Nkx2.5* story provides a dramatic example of the dedication of a particular transcription factor to a particular organ during half a billion years or so of evolutionary divergence. It also illustrates the value of *Drosophila* and other model organisms for discovering human genes involved in disease. Finally it shows that organs that serve the same purpose but look really different, like insect and mammalian hearts, may nonetheless be built using some of the same molecular regulators.

In order to form a functioning pump, the mammalian heart tube bends and twists in an asymmetric way. This looping brings together chamber primordia in such a way that openings can form between some of them (see Figure 22-18c, d). These openings will become valves. The bending and looping of the heart can happen in a left- or right-handed way depending, as we shall see, on information inherited from earlier asymmetric gene expression. Figure 22-19 shows a mouse mutant with reversed heart direction.

Among the mutations that cause left-right errors are some that affect the formation and function of cilia. We have already mentioned Kartagener's syndrome, in which mutations in the motor protein dynein can cause left-right reversal of the heart as well as male infertility due to immotile sperm flagella. These and other findings suggested a role of cilia or flagella in controlling left-right asymmetry. In the mouse, the relevant cilia turn out to be in the node (Figure 22-20a), the region in mammalian embryos that is more or less equivalent to the Spemann organizer in amphibians. The biased motion of cilia in the node causes fluids and signals to flow toward the left (Figure 22-20b). It is not yet clear that the asymmetry driven by the cilia is the very earliest left-right

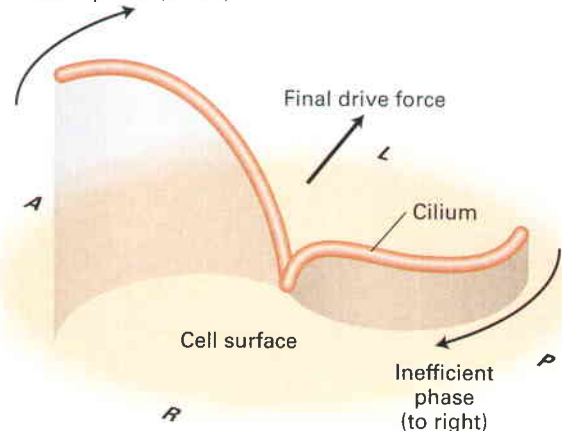

▲ **FIGURE 22-19 Normal and “reversed” hearts.** Hearts are genetically programmed to loop in a particular direction. In the normal mouse heart shown here, the looping is opposite to that of the heart from an *iv* mutant mouse, as indicated by the arrows. The *iv* gene encodes a dynein motor protein that is necessary for proper left-right asymmetry of the heart. [Copyright Oxford University Press, N. Brown.]

difference in all animals, since evidence exists for asymmetries that precede node formation. The cilia hypothesis is strongly supported by genetic analyses that in an unbiased way screened for left-right developmental defects.

The mystery of what is moved by the nodal cilia may have been resolved with the recent discovery of nodal vesicle particles (NVPs), which are 0.35- to 0.5- μm in diameter. NVPs contain Sonic hedgehog protein and retinoic acid, both known to be powerful regulators of cell fates. In response to FGF signals, NVPs are released from cells and are moved to the left side of the node where they stimulate heightened Ca^{2+} levels, one aspect of “leftness.” The movement of the NVPs and/or other substances results in asymmetric expression of genes encoding TGF β signals and consequent left-only

(b) Efficient phase (to left)

▲ **FIGURE 22-20 Role of cilia at the node in controlling left-right polarity in mammalian embryos.** (a) Mouse embryo at 8 days (*left*) and high magnification view of the node (*right*) showing cilia. A = anterior; P = posterior; L = left; R = right. (b) Model of cilia function. The cilia more effectively move fluid, and the signaling proteins carried by it, in the “power stroke” toward the left. The “recovery stroke” toward the right is inefficient in moving fluid. Thus the inherent asymmetry of the motor apparatus inside tiny cilia leads to the asymmetry of our entire body. [Part (a) from H. Hamada et al., 2002, *Nature Genetics* 3:103. Part (b) adapted from S. Nonaka et al., 2005, *PLoS Biology* 3:268.]

expression of the *Pitx2* gene, which encodes a transcription factor. These regulatory events set in motion the regulatory processes that give rise to different cell arrangements, and eventually organ structures, on the left and right sides.

KEY CONCEPTS OF SECTION 22.3

Cell Diversity and Patterning in Early Vertebrate Embryos

- The fertilized egg is a totipotent cell, which can give rise to all the kinds of cells in the body.
- Cleavage of the fertilized egg is a series of rapid cell divisions, initially giving rise to a clump of similar-looking cells (see Figure 22-8). By the time 64 cells have formed in mammalian embryos, some cells have moved to the outside, constituting the trophoblast, while others remain inside as the inner cell mass.
- The trophoblast will form extra-embryonic tissues like the placenta, and the inner cell mass (ICM) will form the embryo itself (see Figure 22-10). The ICM is the source of embryonic stem cells.
- Since most somatic cells have a complete (diploid) genome, cell differentiation usually does not depend on the physical loss of some genes. One exception is lymphocytes, in which portions of the genome are rearranged or lost during development.
- The inner cell mass, a clump of undifferentiated cells, begins to form multiple cell layers during gastrulation. Initially the cells form two layers and then cells in one layer move into the middle to form a third layer. This gives rise to the three germ layers: endoderm, mesoderm, and ectoderm (see Figure 22-11).
- Several signal-emitting centers form in early vertebrate embryos (see Figures 22-12 and 22-16). Cells that receive the signals, usually integrating more than one, activate certain genes in response. Secreted protein signals and signal antagonists coming from these centers thus determine cell fates along the anterior-posterior and dorsal-ventral axes.
- Signals that control cell fates in a dose-dependent way are called morphogens. In the case of such signals, receiving cells take on one fate at high levels; different fates at moderate levels; and a third, default fate in the absence of the signal.
- Antagonists of signals are important in restraining and balancing the effects of powerful inductive signals (see Figure 22-15). For example, mesoderm induction by TGF β is prevented in regions of the embryo where the nervous system will form by secreted protein antagonists that compete with TGF β .
- During gastrulation, differences in gene expression from left to right become evident (see Figure 22-17). This left-right polarized gene expression depends in part on cilia at the node, a depression at the anterior end of the primitive streak. These cilia appear to move signals to one side more than to the other (see Figure 22-20), setting in motion distinct cell fate decisions on the two sides of the embryo.

22.4 Control of Body Segmentation: Themes and Variations in Insects and Vertebrates

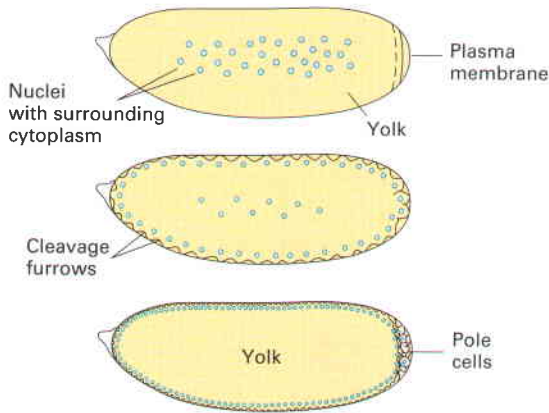

Forming structure and pattern in animals involves more than creating tissue types and determining head to tail, side to side, and front to back polarities. Insects, vertebrates, and many other creatures have repeating body parts. Indeed, vertebrates are named for the repeating bones (vertebrae) that make up the spinal column. Such repeating body parts are usually not perfectly identical; rather, they exhibit themes and variations that are functional for the animal. For example, some of our vertebrae have ribs attached, and others do not. When a wasp visits your picnic, the striped segments of its body are clearly visible. Some of the segments of an insect body have legs and others do not. In this section, we examine the genetic regulation of embryo segmentation in an insect and in a vertebrate to see two different ways to create a repeating pattern. Then we will look at genes that control the differences among the repeats. Remarkably, segment-specific differences are controlled by the same genes in insects and vertebrates, despite the half billion years or so since their common ancestor was alive.

The study of the molecular cell biology of body segmentation began with a powerful genetic screen designed to systematically identify every gene needed to form the segments in *Drosophila*. This sort of systematic screening had been applied to identifying components of more specific processes such as mating-type regulation in yeast, but had never before been applied to the development of a large complicated animal. The screen was enormously successful in identifying segmentation genes, opening up a new era of molecular analysis of pattern formation, one aspect of the generation of form (*morphogenesis*). Startlingly, though, the screen succeeded far beyond expectations in two ways: it identified many genes involved in development of internal tissues, not only the segmented outer skeleton, and the genes identified in flies turned out to be representative of genes used in all animals to control embryonic development. Since then systematic genetic screens have been applied to many other developmental and cell biological processes, such as neural and heart development, using a variety of model organisms including worms, flies, mice, and zebrafish (see Figure 1-25). As a consequence, the genes being identified in various genome projects can increasingly be described in terms of their functions, as well as the tissues, times, and processes in which they participate. That is a crucial step in understanding the whole network of regulators that drives development.

To understand how segmentation arises, we first describe early *Drosophila* development and then discuss the types and functions of genes that were found in the original genetic screen. Next we examine the segmentation process in vertebrates and finally conclude this section by considering pattern formation in plants.

(b) Cellularization

Cellular blastoderm

FIGURE 22-21 Formation of the cellular blastoderm during early *Drosophila* embryogenesis. Stages from the syncytium (a) to cellular blastoderm (b) are illustrated in diagrams and electron micrographs. Nuclear division is not accompanied by cell division until about 6000 nuclei have formed and migrated outward to the plasma membrane. Before cellularization, the embryo displays surface bulges overlying individual nuclei, which remain within a common cytoplasm. No membranes other than that surrounding the entire embryo are present. After cellularization, cell membranes are evident around individual nuclei. Note the segregation of the nuclei of so-called pole cells, which give rise to germ-line cells, at the posterior end of the syncytial blastoderm. [Photographs courtesy of A. P. Mahowald; diagrams after P. A. Lawrence, *The Making of a Fly*, 1992, Blackwell Scientific, Oxford.]

the blastula, whose interior is filled with yolk. Soon some of the epithelial cells move inside, the insect version of gastrulation, and eventually develop into the internal tissues.

In all animals, many of the important pattern-controlling regulators act when the embryo has relatively few cells. The fly blastula, for instance, is only about 100 cells long and 60 cells in circumference, but even at this early stage, the major parts of the body plan are laid out. Because the fly embryo is a syncytium for the first few hours of development, regulatory molecules can move in the common cytoplasm without having to cross plasma membranes. Some molecules form gradients, which are used in the earliest stages of cell-fate determination in *Drosophila* before subdivision of the syncytium into individual cells. Thus transcription factors, as well as secreted molecules, can function as morphogens in the syncytial fly embryo. Within 1 day of fertilization, an amazingly short time to form a whole organism, the embryo develops into a segmented larva (juvenile stage) that lacks wings and legs. Development continues through three larval stages (≈ 4 days total) and the ≈ 5 -day pupal stage during which metamorphosis takes place and adult structures are created (Figure 22-22a). At the end of pupation, about 10 days after fertilization, the pupal case splits and an adult fly emerges.

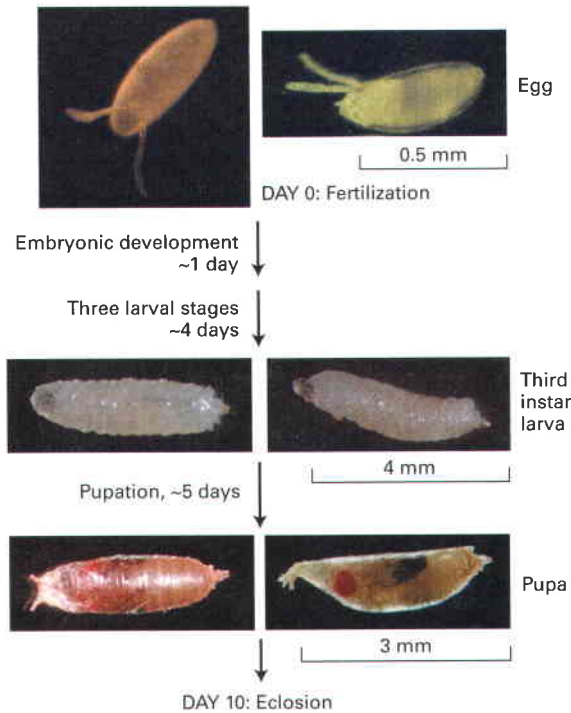

The initially equivalent cells of the syncytial embryo rapidly begin to assume different fates, leading to a well-ordered pattern of distinct cell identities. These early patterning events set the stage for the later development and proper placement of different tissues (e.g., muscle, nerve, epidermis) and body parts, as well as the shapes of the appendages and the organization of cell types within them. The early embryo is symmetric side to side, and the initial differences among cells are created along the dorsal-ventral (back-front) and anterior-posterior (head-tail) axes. During the larval stages, groups of ectodermal cells, called *imaginal discs*, form at specific sites and stay largely quiescent during early larval stages (Figure 22-22b). Each disc will grow and give rise to specific adult structures during pupation, one for each wing, one for each leg, and so forth.

Different sets of genes are active in establishing cell fates along the dorsal-ventral (back-front) and anterior-posterior (head-tail) axes. The initial fate of every cell is governed by both dorsal-ventral-acting and anterior-posterior-acting regulators in a kind of two-dimensional grid. Both regulatory systems begin with information and molecules contributed

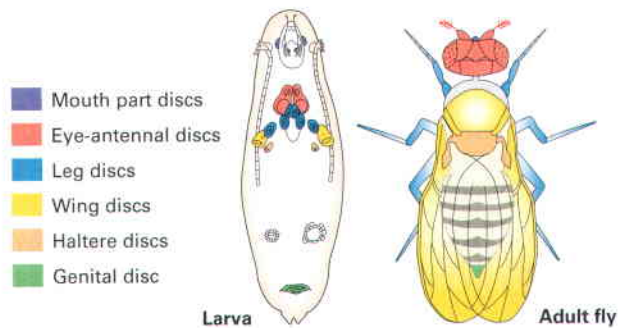

Early *Drosophila* Development Is an Exercise in Speed

After fertilization and fusion of male and female pronuclei in *Drosophila*, the first 13 nuclear divisions of the zygote are synchronous and rapid, each division occurring about every 10 minutes. This DNA replication is the most rapid known for a eukaryote, with the entire 160 Mb of *Drosophila* chromosomal DNA copied in a cell-cycle S phase that lasts only 3 minutes. Because these nuclear divisions are *not* accompanied by cell divisions, they generate a multinucleated egg cell, a **syncytium**, with a common cytoplasm and plasma membrane (Figure 22-21a). As the nuclei divide, they begin to migrate outward toward the plasma membrane. The nuclei reach the surface about 2–3 hours after fertilization, forming the *syncytial blastoderm*; during the next hour or so, cell membranes form around the nuclei, generating the cellular blastoderm, or blastula (Figure 22-21b). All future tissues are derived from the 6000 or so epithelial cells on the surface of

(a) *Drosophila* developmental stages

(b) Imaginal discs, precursors to the adult

▲ FIGURE 22-22 Major stages in the development of *Drosophila* and location of imaginal discs.

(a) The fertilized egg develops into a blastoderm and undergoes cellularization in a few hours. The larva, a segmented form, appears in about 1 day and passes through three stages (instars) over a 4-day period, developing into a prepupa. Pupation takes \approx 4–5 days, ending with the emergence of the adult fly from the pupal case. (b) Groups of ectodermal cells called imaginal discs are set aside at specific sites in the larval body cavity. During pupation, these give rise to the various body parts indicated. Other precursor cells give rise to adult muscle, the nervous system, and other internal structures. [Part (a) courtesy Kaye Suyama. Part (b) adapted from J. W. Fristrom et al., 1969, in E. W. Hanly, ed., *Park City Symposium on Problems in Biology*, University of Utah Press, p. 381.]

to the oocyte as a dowry from the mother. The dorsal-ventral control system involves differential transport of a transcription factor called Dorsal into the nuclei of the syncytial embryo. This transcription factor, related to the vertebrate NF- κ B protein, is present in its inactive form throughout the cytoplasm of the syncytial embryo. A signal protein concentrated on the ventral side of the embryo triggers the NF- κ B signaling pathway (see Figure 16-35), leading to activation

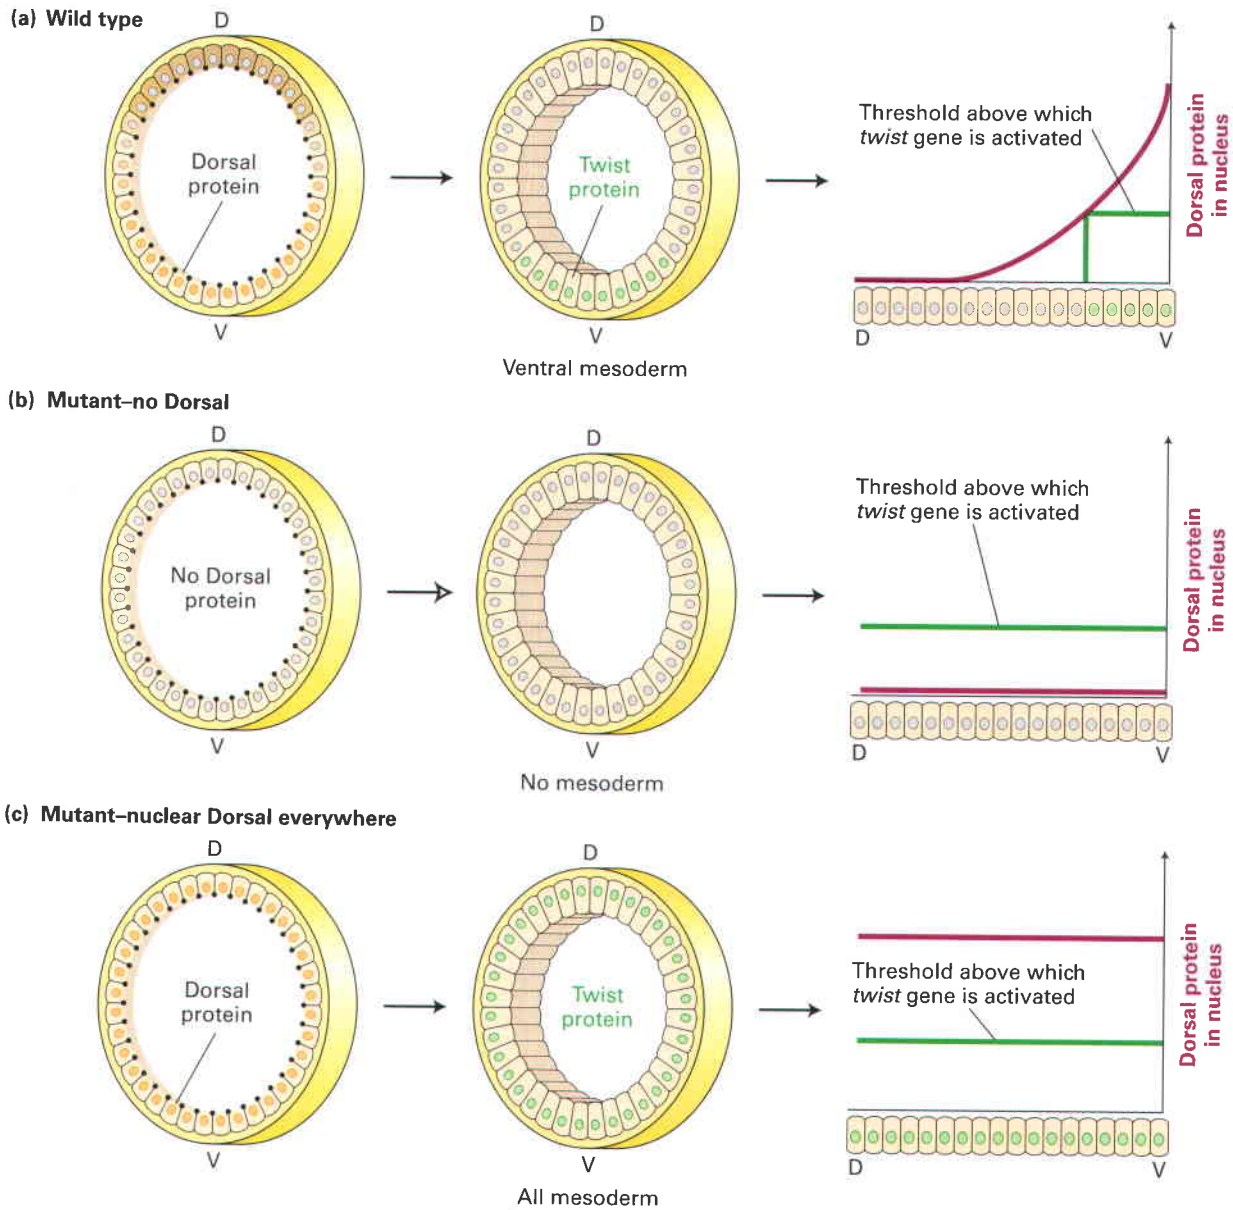

of Dorsal and its translocation into nuclei. As a result, Dorsal enters ventral nuclei at a high level, lateral nuclei at a modest level, and dorsal nuclei not at all (Figure 22-23). Thus Dorsal acts in a graded fashion and has the property of a morphogen, even though this protein is not secreted. The differential entry of the Dorsal transcription factor into nuclei, which controls subsequent cell fates, is governed by a complex signaling process that starts during oogenesis in the follicle cells and is transmitted to the developing embryo. We will not pursue the details of dorsal-ventral patterning further and will instead concentrate on anterior-posterior patterning.

To decipher the molecular basis of cell-fate determination and patterning along the three body axes, investigators have cloned genes identified in screens for mutations that affect the body plan; determined the spatial and temporal patterns of mRNA production for each gene and the distribution of the encoded proteins in the embryo; and assessed the effects of mutations on cell differentiation, tissue patterning, and the expression of other regulatory genes. The principles of cell-fate determination and tissue patterning learned from *Drosophila* have proved to have broad applicability to animal development.

Transcriptional Control Specifies the Embryo's Anterior and Posterior

We turn now to determination of the anterior-posterior axis in the early fly embryo while it is still a syncytium. The process begins during oogenesis when *maternal mRNAs* produced by nurse cells are transported into the oocyte and become localized in discrete spatial domains (see Figure 22-2). For example, *bicoid* mRNA is trapped at the most anterior region, or anterior pole, of the early fly embryo (Figure 22-24). The anterior localization of *bicoid* mRNA depends on its 3'-untranslated end and three maternally derived proteins. Embryos produced by female flies that are homozygous for *bicoid* mutations lack anterior body parts, attesting to the importance of Bicoid protein in specifying anterior cell fates.

Bicoid protein is a homeodomain-type transcription factor that activates expression of certain anterior-specific genes discussed later. In the syncytial fly embryo, Bicoid protein spreads through the common cytoplasm away from the anterior end where it is produced from the localized mRNA. As a result, a Bicoid protein gradient is established along the anterior-posterior axis of the syncytial embryo. Since the effects of Bicoid are concentration-dependent, it is acting as a morphogen. Evidence that the Bicoid protein gradient determines anterior structures was obtained through injection of synthetic *bicoid* mRNA at different locations in the embryo. This treatment led to the formation of anterior structures at the site of injection, with progressively more posterior structures forming at increasing distances from the injection site. Another test was to make flies that produced extra anterior Bicoid protein; in these flies, the anterior structures expanded to occupy a greater proportion of the embryo.

▲ EXPERIMENTAL FIGURE 22-23 A gradient of the transcription factor Dorsal directs dorsal-ventral cell fates in the early embryo. Dorsal is the *Drosophila* homolog of vertebrate NF- κ B (See Figure 16-35). (a) In wild-type embryos, more Dorsal protein enters the nuclei on the ventral side. Once inside a nucleus, Dorsal activates target genes such as *twist*, which encodes a transcription factor that directs mesoderm formation. The differential entry of Dorsal thus

creates a dorsal-ventral polarity in *twist* expression and mesoderm induction. Inactive cytoplasmic NF- κ B on the dorsal side fails to activate *twist*. (b) A mutant lacking Dorsal makes no mesoderm cells. (c) Conversely, in a mutant that has Dorsal in the nuclei of all cells, all cells differentiate as mesoderm. [Adapted from L. Wolpert et al., *Principles of Development*, 2nd edition, Oxford Press, Figure 5-14.]

Bicoid protein promotes transcription of the *hunchback* (*hb*) gene from the embryo's genome. Transcription of *hunchback* is greatest in the anterior of the embryo where the Bicoid concentration is highest. Mutations in *hunchback* and several other genes in the embryo's genome lead to large gaps in the anterior-posterior pattern of the early embryo; hence these genes are collectively called **gap genes**. Several types of evidence indicate that Bicoid protein directly regulates transcription of *hunchback*. For example, increasing the number of copies of the *bicoid* gene expands the Bicoid and Hunchback (Hb) protein gradients posteri-

orly in parallel (Figure 22-25a-c). Analysis of the *hunchback* gene revealed that it contains three low-affinity and three high-affinity binding sites for Bicoid protein. Experiments with synthetic genes containing either all high-affinity or all low-affinity Bicoid-binding sites demonstrated that the affinity of the site determines the threshold concentration of Bicoid at which gene transcription is activated (Figure 22-25d, e). In addition, the number of Bicoid-binding sites occupied at a given concentration has been shown to determine the amplitude, or level, of the transcription response.

◀ **EXPERIMENTAL FIGURE 22-24** Maternally derived *bicoid* mRNA is localized to the anterior region of early *Drosophila* embryos. All embryos shown are positioned with anterior to the left and dorsal at the top. In this experiment, in situ hybridization with a radioactively labeled RNA probe specific for *bicoid* mRNA was performed on whole-embryo sections 2.5–3.5 hours after fertilization. This time period covers the transition from the syncytial blastoderm to the beginning of gastrulation. After excess probe was removed, probe hybridized to maternal *bicoid* mRNA (dark silver grains) was detected by autoradiography. Bicoid protein is a transcription factor that acts alone and with other regulators to control the expression of certain genes in the embryo's anterior region. [From P. W. Ingham, 1988, *Nature* **335**:25; photographs courtesy of P. W. Ingham.]

Findings from studies of Bicoid's ability to regulate transcription of the *hunchback* gene show that variations in the levels of transcription factors, as well as in the number or affinity of specific regulatory sequences controlling different target genes, or both, contribute to generating diverse patterns of gene expression during *Drosophila* development. Similar mechanisms are employed in other developing organisms.

Translation Inhibitors Reinforce Anterior-Posterior Patterning

Cell fates at the posterior end of the fly embryo are specified by a different mechanism—one in which control is at the

translational level rather than the transcriptional level. As just discussed, transcription of the embryo's *hunchback* gene, which promotes anterior cell fates, produces an anteriorly located band of *hunchback* mRNA and Hunchback protein because of the anterior → posterior gradient of maternally derived Bicoid protein. In addition, however, the early embryo contains *hunchback* mRNA synthesized by nurse cells. Even though this maternal *hunchback* mRNA is uniformly distributed throughout the embryo, its translation is prevented in the posterior region by another maternally derived protein called Nanos, which is localized to the posterior end of the embryo. The set of genes required for posterior localization of Nanos protein is also required for germ-line cells to form at the posterior end of the embryo. One of these genes (*staufer*) is necessary for development of primordial germ cells (PGCs) in zebrafish. Thus at least some germ-line regulators have existed since fish and flies had a common ancestor.

◀ **EXPERIMENTAL FIGURE 22-25** Maternally derived Bicoid controls expression of the embryonic *hunchback* (*hb*) gene along the anterior-posterior axis. (a–c) Increasing the number of *bicoid* genes in mother flies changed the Bicoid gradient in the early embryo, leading to a corresponding change in the gradient of Hunchback protein produced from the *hunchback* gene in the embryo's genome. The *hunchback* promoter contains three high-affinity and three low-affinity Bicoid-binding sites. Transgenic flies carrying a reporter gene linked to a synthetic promoter containing either four high-affinity sites (d) or four low-affinity sites (e) were prepared. In response to the same Bicoid protein gradient in the embryo, expression of the reporter gene controlled by a promoter carrying high-affinity Bicoid-binding sites extended more posteriorly than did transcription of a reporter gene carrying low-affinity sites. This result indicates that the threshold concentration of Bicoid that activates *hunchback* transcription depends on the affinity of the Bicoid-binding site. Bicoid regulates other target genes in a similar fashion. [Adapted from D. St. Johnston and C. Nüsslein-Volhard, 1992, *Cell* **68**:201.]

Figure 22-26 illustrates how translational regulation by Nanos helps to establish the anterior → posterior Hunchback gradient needed for normal fly development. Translational repression of *hunchback* mRNA by Nanos depends

▲ **FIGURE 22-26** Role of Nanos protein in excluding maternally derived Hunchback (Hb) protein from the posterior region of *Drosophila* embryos. (a) Both *nanos* (blue) and *hunchback* (red) mRNAs derived from the mother are distributed uniformly in the fertilized egg and early embryo. Nanos protein, which is produced only in the posterior region, subsequently inhibits translation of maternal *hb* mRNA posteriorly. (b) Diffusion of Nanos protein from its site of synthesis in the posterior region establishes a posterior → anterior Nanos gradient. A complex of Nanos and two other proteins inhibits translation of maternal *hb* mRNA. As a consequence, maternally derived Hb protein is expressed in a graded fashion that parallels and reinforces the Hb protein gradient resulting from Bicoid-controlled transcription of the embryo's *hb* gene (see Figure 22-25). [See C. Wreden et al., 1997, *Development* 124:3015.]

on a specific sequence in the 3'-untranslated region of the mRNA, the Nanos-response elements (NRE). Along with two other RNA-binding proteins, Nanos binds to the NRE in *hunchback* mRNA. The results of genetic and molecular studies suggest that Nanos promotes deadenylation of *hunchback* mRNA and thereby decreases its translation. In the absence of Nanos, the accumulation of maternal Hb protein in the posterior region leads to failure of the posterior structures to form normally, and the embryo dies. Conversely, if Nanos is produced in the anterior, thereby inhibiting the production of Hb from both maternal and embryonic *hunchback* mRNA, anterior body parts fail to form, again a lethal consequence. Translational control due to the action of an inhibitor, mRNA localization, or both, may be a widely used strategy for regulating development. For instance, specific mRNAs are localized during the development of muscle cells, and during cell division in the budding yeast *Saccharomyces cerevisiae* (see Figure 21-28).

Insect Segmentation Is Controlled by a Cascade of Transcription Factors

In both insects and vertebrates, the anterior-posterior (head-tail) axis is divided into a set of repeats, or more precisely repeats with variations: vertebrae and associated ganglia in vertebrates, body segments in insects. Specific genes control subdivision of the embryo into repeats, while other genes control the differences between repeats. As noted already, not all vertebrae have attached ribs, and only some of an insect's body segments have legs growing from them. We discuss the genes controlling segmentation of insects in this section and the rather different type of regulation underlying vertebrate segmentation in the next section. Then we delve into the genes that control differences between segments.

Once the gap genes have been properly activated in the *Drosophila* embryo, the next steps on the road to body segmentation are controlled by a *transcription-factor (TF) cascade* in which one TF controls a gene encoding another TF, which in turn controls expression of a third TF. At each step, more than one gene may be regulated. Such a TF cascade can generate a population of cells that may all look alike but differ at the transcriptional level. TF cascades have both a temporal and a spatial dimension. At each step in a cascade, for instance, RNA polymerase and ribosomes can take more than an hour to produce a transcription factor from its corresponding mRNA. Spatial factors come into play when cells at different positions within an embryo synthesize different transcription factors.

The rough outline of cell fates that is laid down in the syncytial fly embryo is refined into a system for precisely controlling the fates of individual cells. Discovery of the relevant regulators came from a genetic screen for mutants with altered embryo body segments. In addition to *hunchback*, four other gap genes—*Krüppel*, *knirps*, *giant*, and *tailless*—are transcribed in specific spatial domains beginning about 2 hours after fertilization (Figure 22-27a). Expression of these genes, like that of *hunchback*, is regulated first by maternal factors and then by cross-interactions among the gap genes.

(b) Hunchback and Krüppel

(c)

(d)

▲ **EXPERIMENTAL FIGURE 22-27** Gap genes and pair-rule genes are expressed in characteristic spatial patterns in early *Drosophila* embryos. Fixed, permeabilized embryos were stained with fluorescence-labeled antibodies specific for a particular protein. All embryos shown are positioned with anterior to the left and dorsal at the top. (a) These syncytial embryos were stained individually for the proteins encoded by four of the five gap genes. Transcription of the *Krüppel*, *knirps*, and *giant* gap genes is regulated by Hunchback, Bicoid, and Caudal. (b) This syncytial embryo was doubly stained to visualize Hunchback protein (red) and Krüppel protein (green). The posterior Hunchback protein visible here is only weakly visible in part (a) due to the plane of focus. The yellow band identifies the region in which production of these two gap proteins overlaps. (c) In this blastoderm-stage embryo, Fushi tarazu (blue) and Even-skipped (brown) proteins, encoded by the pair-rule genes *ftz* and *eve*, respectively, are expressed in stripes. Each stripe corresponds to the primordial cells of one body segment. Altogether about 14 segments

are formed. No morphological evidence of segmentation can be seen at this stage, but staining for the RNA or protein products of pair-rule genes reveals the beginnings of a segmented body plan. (d) The relationship between the early segment primordia (lower embryo), expression stripes of one pair-rule gene (dark gray), and the eventual larval segments that are formed (upper larva) is depicted. The colors indicate the different segments, from head to tail, and how they correspond from embryo to larva. The larval head is barely visible externally. Note that each segment develops from a primordium that is about four cells wide (in the head-to-tail direction) and about 60 cells around. Half of the segments develop from cells that express the pair-rule gene and half from the “interstripes” that do not; the interstripes express a different pair-rule gene. T = thoracic segments; A = abdominal segments. [Part (a) adapted from G. Struhl et al., 1992, *Cell* 69:237. Part (b) courtesy of M. Levine. Part (c) courtesy of Peter Lawrence. Part (d) courtesy of Nipam Patel.]

All the gap-gene proteins are transcription factors. Because these proteins are distributed in broad overlapping peaks (Figure 22-27b), each cell along the anterior-posterior axis contains a particular combination of gap-gene proteins that activates or represses specific genes within that cell. Indeed, something like a battle ensues, because some gap proteins repress the transcription of genes encoding other gap proteins. Although they have no known extracellular ligands, some gap proteins resemble **nuclear receptors**, which are intracellular proteins that bind lipophilic ligands (e.g., steroid hormones) capable of crossing the plasma membrane. Most ligand–nuclear re-

ceptor complexes function as transcription factors (see Figure 7-50). The sequence similarity between gap proteins and nuclear receptors suggests that gap genes may have evolved from genes whose transcription was controlled by signals that could cross membranes, such as the steroid hormones. The use of such signal-controlled genes, rather than TF cascades, could explain how early cell-fate specification operates in animals that do not have a syncytial stage.

The fates of cells distributed along the anterior-posterior axis are specified early in fly development. At the same time, cells are responding to the dorsal-ventral control system.

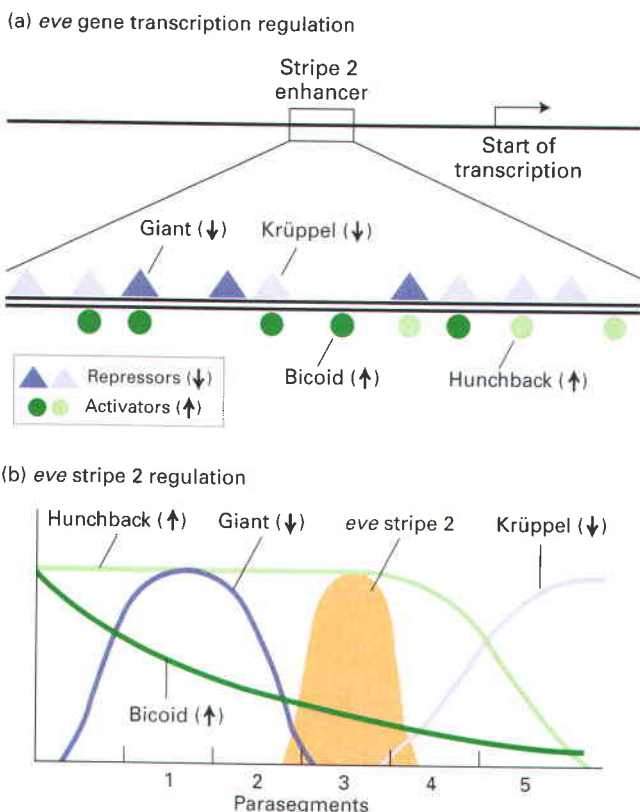

Each cell is thus uniquely specified along both axes. If each of the five gap genes were expressed in its own section of the embryo, at just one concentration, only five cell types could be formed. The actual situation permits far greater diversity among the cells. The amount of each gap protein varies from low to high to low along the anterior-posterior axis, and the expression domains of different gap genes overlap. This complexity creates combinations of transcription factors that lead to the creation of many more than five cell types. Remarkably, the next step in *Drosophila* development generates a repeating pattern of cell types from the rather chaotic non-repeating pattern of gap-gene expression domains.

The first sign of segmentation in fly embryos is a pattern of repeating stripes of transcription of eight genes collectively called **pair-rule genes** (Figure 22-27c). The body of a larval fly consists of 14 segments, and each pair-rule gene is transcribed in half of the segment primordia, or seven stripes, separated by “interstripes” where that pair-rule gene is not transcribed (Figure 22-27d). Mutant embryos that lack the function of a pair-rule gene have their body segments fused together in pair-wise fashion—hence the name of this class of genes. The expression stripes for each pair-rule gene partly overlap with those of other pair-rule genes; so each gene must be responding in a unique way to gap-gene and other earlier regulators.

The transcription of pair-rule genes is controlled by transcription factors encoded by gap and maternal genes. Because gap and maternal genes are expressed in broad, non-repeating bands, the question arises: How can such a non-repeating pattern of gene activities confer a repeating pattern such as the striped expression of pair-rule genes? To answer this question, we consider the transcription of the *even-skipped (eve)* gene in stripe 2, which is controlled by the maternally derived Bicoid protein and the gap proteins Hunchback, Krüppel, and Giant. All four of these transcription factors bind to a clustered set of regulatory sites, or **enhancer**, located upstream of the *eve* promoter (Figure 22-28a). Hunchback and Bicoid activate the transcription of *eve* in a broad spatial domain, whereas Krüppel and Giant repress *eve* transcription, thus creating sharp posterior and anterior boundaries. The combined effects of these proteins, each of which has a unique concentration gradient along the anterior-posterior axis, initially demarcates the boundaries of stripe 2 expression (Figure 22-28b).

Expression of the other *eve* stripes also depends on specific enhancers. Each stripe of *eve* expression is formed in response to a different combination of transcriptional regulators acting on a specific enhancer, so the *non-repeating* distributions of regulators create *repeating* patterns of pair-rule gene repression and activation. If even one enhancer is bound by an activating combination of transcriptional

Video: Establishing *Eve* Expression in *Drosophila* Embryogenesis

◀ **FIGURE 22-28 Control of *even-skipped (eve)* stripe 2 in the *Drosophila* embryo.** Only one of the *eve* gene stripes is represented. Within each *eve* stripe, a segment boundary will later form. Thus *eve* function gives rise to half the segment boundaries in the embryo. (a) Diagram of the 815-bp enhancer controlling transcription of the pair-rule gene *eve* in stripe 2. This regulatory region contains binding sites for Bicoid and Hunchback proteins, which activate the transcription of *eve*, and for Giant and Krüppel proteins, which repress its transcription. The enhancer is shown with all binding sites occupied, but in an embryo occupation of sites will vary with position along the anterior-posterior axis. (b) Concentration gradients of the four transcription factors that regulate *eve* stripe 2. The coordinated effect of the two repressors (↓) and two activators (↑) determine the precise boundaries of the second anterior *eve* stripe. Only in the orange region is the combination of regulators correct for the *eve* gene to be transcribed in response to the stripe 2 control element. Further anterior, Giant turns *eve* off; further posterior, the level of Bicoid activator is too low to overcome repression by Krüppel. Expression of other stripes is regulated independently by other combinations of transcription factors that bind to enhancers not depicted in part (a). [See S. Small et al., 1991, *Genes & Devel.* 8:827.]

regulators, the presence of other enhancers in an inactive, “off” state (not bound to a regulator) will not prevent transcription. For instance, in *Eve* stripe 2, the right combination and amounts of Hunchback and Bicoid create an “on” state that activates transcription even though other enhancers are present in the inactive state. In each stripe, at least one enhancer is bound by an activating combination of regulators. Note that this system of gene control is flexible and could be used to produce non-repeating patterns of transcription if that was useful to an animal.

Similar responses to gap and maternal proteins govern the striped patterns of transcription of the two other pair-rule genes, *runt* and *hairy*. Because the enhancers of *runt* and *hairy* respond to different combinations of regulators, the *eve*, *runt*, and *hairy* expression stripes partly overlap one another, with each stripe for any one gene offset from a stripe for another gene. Subsequently, other pair-rule genes, including *fushi tarazu* (*ftz*) and *paired*, become active in response to the *Eve*, *Runt*, and *Hairy* proteins, which are transcription factors, as well as to maternal and gap proteins. The outcome of this transcription-factor cascade is a pattern of overlapping stripes.

The initial pattern of pair-rule stripes, which is not very sharp or precise, is sharpened by autoregulation. The *Eve* protein, for instance, binds to its own gene and increases transcription in the stripes, a positive autoregulatory loop. This enhancement does not occur at the edges of stripes where the initial *Eve* protein concentration is low; so the boundary between stripe and interstripe is fine-tuned.

The pair-rule genes direct formation of the embryo’s segment boundaries. Since each pair-rule gene is expressed in stripes and each stripe overlaps one segment boundary, each pair-rule gene contributes to half the segment boundaries. Acting together, all the pair-rule genes form all the segment boundaries and also control other pattern elements within each segment. In early embryos each segment primordium is about four cells wide along the anterior-posterior axis, which corresponds to the approximate width of pair-rule expression stripes. With pair-rule genes active in alternating four-on four-off patterns, the repeat unit is about eight cells. Each cell expresses a combination of transcription factors that can distinguish it from any of the other seven cells in the repeat unit. Under the control of pair-rule proteins and the later-acting **segment-polarity genes**, the repeating morphology of segments begins to emerge; it is completed about 10 hours after fertilization. As cell-fate determination progresses in the fly embryo, a variety of signaling proteins begin to play a role. These include Hedgehog and Wnt, which are encoded by segment-polarity genes and are produced in stripes, one stripe within each segment, under the control of pair-rule gene products. The broader and earlier-formed stripes of pair-rule gene expression overlap in certain regions, and that’s where particular combinations of pair-rule transcription factors give rise to the fine pattern of segment-polarity gene stripes. Note that the onset of signal-based controls allows cells to respond to what their neighbors have done and make adjustments. Otherwise parts of the pattern might be missing or duplicated.

From the broad maternal gradient of Bicoid to the single-cell precision of the segment-polarity genes, the fly embryo is progressively subdivided into repeating units. One can readily imagine how changes in stripe-specific enhancers, amounts of particular transcription factors, and the range of signals during evolution could modify the pattern of segments in different organisms.

Vertebrate Segmentation Is Controlled by Cyclical Expression of Regulatory Genes

Now we return to vertebrates to examine how segmentation in these animals compares with that in insects. After the three body axes have been established in a vertebrate embryo, dramatic changes take place along all of them. One of the most visible changes is the initiation of a repeating pattern that later gives rise to vertebrae and ribs. This is patterning along the anterior (head) to posterior (tail) axis. In mice and humans, the first sign of the vertebrae appears in the mesoderm that accumulates under the primitive streak. The mesoderm forms, you will recall, by an epithelial-mesenchymal transition in which cells along the primitive streak cut loose and migrate inside (see Figure 22-11). On each side of the midline axis, mesoderm composed of loose mesenchymal cells begins to round up to form pairs of spherical epithelia called *somites*. Somites initially form at the anterior and successively appear pair by pair in the posterior direction (Figure 22-29a), giving them value as a way to stage embryos. This striking case of a mesenchymal-epithelial transition has huge consequences for the embryo. From somites come the vertebrae and ribs, the muscles of the body wall and limbs, and the dermis (inner skin) of the back. Without somites, we would be blobs.

The mesoderm that has not yet formed somites is called *presomitic mesoderm*. As gastrulation spreads toward the posterior, somites arise from presomitic mesoderm, and more presomitic mesoderm forms posteriorly. The interplay of four signaling systems at the anterior limit of the presomitic mesoderm controls somite formation: an FGF signal from the tail, a retinoic acid signal from the head, and Wnt and Notch signals within the presomitic mesoderm. The *fgf8* gene is expressed in the presomitic mesoderm where it is forming near the posterior tip of the embryo. Because *fgf8* mRNA is unstable, the highest level of FGF8 protein builds up in the posterior and forms a gradient toward the anterior. High levels of FGF8 prevent maturation of cells into somites in the posterior. Conversely, retinoic acid from the head of the embryo acts in a graded fashion, highest in the anterior presomitic mesoderm, to stimulate formation of somites (Figure 22-29b).

The most remarkable aspect of somite-formation regulation in vertebrates was first discovered in studies of the chicken gene *hairy1*, which is related to one of the *Drosophila* pair-rule segmentation genes. In situ hybridization of developing somites in chick embryos showed that *hairy1* transcripts are produced in cycles, with the duration of one cycle corresponding to the time it takes to form one somite (90 minutes in a chick, longer in mammals). A wave

(a) Early embryo (5 pairs of somites)

Late embryo (9 pairs of somites)

▲ **FIGURE 22-29 Progressive formation of somites in human embryos.** (a) Five pairs of somites have formed at the anterior of the earlier embryo on the left. Somite formation proceeds toward the posterior, and in the later embryo on the right, nine pairs have formed. In both micrographs, the developing head is on the left and the tail bud on the right. (b) Gradients of FGF8, a secreted protein made in the tail

bud, and retinoic acid from the head, control somite formation from presomitic mesoderm, which first arises in the tail bud. High levels of FGF8 prevent maturation of presomitic cells into somites in the posterior, whereas high levels of retinoic acid acts to stimulate formation of somites. [Part (a) Kohei Shiota/Congenital Anomaly Research Center, Kyoto University. Part (b) adapted from A. F. Schier, 2004, *Nature* **427**:403.]

of *hairy1* expression moves from posterior to anterior in the presomitic (unsegmented) mesoderm. Subsequent investigations revealed a rather large number of genes that undergo cycles of expression, and all turned out to be related to the Notch or Wnt signaling pathways. Mutations in either pathway cause drastic defects in somite formation. In humans, for instance, mutations affecting Notch pathway components cause Alagille syndrome and Jarcho-Levin syndrome, both of which are associated with malformed vertebrae.

For both the Notch and Wnt pathways, feedback loops are established that cause temporal cycling of expression. For example, the *hes7* gene encodes a transcription factor involved in Notch signal transduction. When transcription of *hes7* is stimulated by a FGF signal from the posterior presomitic mesoderm, a burst of Hes7 protein production occurs (Figure 22-30a). Hes7 protein, in turn, controls the expression of target genes that contribute to somite formation. Because Hes7 also acts as a repressor of its own gene, binding to its gene and turning it off, the Hes7 protein accumulates only until it reaches a high enough level to represses *hes7* transcription. This negative autoregulation thus limits the duration of *hes7* expression. Each part of the presomitic mesoderm does the same thing in turn: *hes7* transcription on, Hes7 protein accumulates, *hes7* transcription off (Figure 22-30b). As the source of the FGF signal starts near the head and retreats posteriorly, *hes7* is transcribed first in the most anterior region, then in progressively more posterior regions. A similar feedback system operates for Wnt signaling, again causing a burst of gene expression just as a somite forms, another burst in the cells that will form the subsequent somite, and so on. If Notch or Wnt feedback loops are blocked, somites are highly abnormal, but the details of how both pathways control shaping of the somites are not known.

We can now understand the two different strategies for controlling the formation of repeating body parts in insects and vertebrates. In *Drosophila*, the regulation differs for each body segment: different combinations of gap transcription factors, activated in specific regions along the anterior-posterior axis by maternal influences, regulate pair-rule gene stripes, and pair-rule transcription factors in turn combine to regulate the still finer stripes of segment-polarity gene transcription. Each stripe has a distinct regulatory history involving different gap or pair-rule proteins. Thus repeat formation is controlled by *spatial* differences. In contrast, repeating vertebrate somites are formed by the same regulatory process occurring again and again. A remarkable feedback system creates a cyclical clock that causes the genes responsible for building somites to be expressed in bursts. Thus repeat formation is controlled by *temporal* (time) differences.

Differences Between Segments Are Controlled by Hox Genes

Despite the differences in how repeating body parts are formed in insects and vertebrates, the two groups of animals are reunited in employing the same family of genes to create variation among the repeats. These are the **Hox genes**, which control differences in cell identities and indeed the identities of whole parts of an animal along the anterior-posterior axis. These differences are superimposed upon the underlying repetitive nature of some of the tissues. Hox genes encode highly related transcription factors containing the **homeodomain** motif (Chapter 7). Indeed, what unifies the whole group of Hox proteins is a similar DNA-binding homeodomain sequence; the proteins have little else in common. The homeodomain sequences are also the basis for classifying all the Hox genes.

▲ **FIGURE 22-30 Control of cyclical gene expression in the developing somites.** (a) An initial burst of *hes7* transcription is triggered by a positive signal, probably FGF8. As Hes7 protein (a Notch pathway component) accumulates, it eventually binds to its own gene and turns off transcription. This process is repeated, once per forming somite, in increasingly posterior regions of the presomitic

mesoderm. (b) The FGF8 signal continues to be at the posterior end, so progressively more posterior presomitic mesoderm is triggered to activate cyclical Notch and Wnt expression programs, leading to somite formation. The red circles represent bursts of transcription of genes encoding Notch and Wnt signaling components and the negative feedback loops that shut them down.

Mutations in Hox genes often cause **homeosis**—that is, the formation of a body part having the characteristics normally found in another part at a different site. For example, some mutant flies develop legs on their heads instead of antennae. Loss of function of a particular Hox gene in a location where it is normally active leads to homeosis if a different Hox gene becomes derepressed there; the result is the formation of cells and structures characteristic of the derepressed gene. A Hox gene that is abnormally expressed where it is normally inactive can take over and impose its own favorite developmental pathway on its new location (Figure 22-31).

Organization of Hox Genes Classical genetic studies in *Drosophila* led to discovery of the first Hox genes (e.g., *Antennapedia* and *Ultrabithorax*). Corresponding genes with similar functions (orthologs) have since been identified in most animal species. Each Hox gene is transcribed in a particular region along the anterior-posterior axis in a remarkable arrangement where the order of genes along the chro-

mosomes is colinear with the order in which they are expressed along the anterior-posterior axis (Figure 22-32a). The fly Hox genes are located at two locations on the same chromosome but are effectively one cluster of eight Hox genes. At one end of the cluster are “head” genes, which are transcribed specifically in the head and are necessary for formation of head structures. Next to them are genes active and functional in the thorax, and at the other end of the cluster are abdomen genes. The arrangement reflects evolutionary gene duplications and is retained because the genes share regulatory sequences such as enhancers (Chapter 7). The expression domains of Hox genes can overlap, so the development of a particular body structure can depend upon more than one gene.

In *Drosophila*, the spatial pattern of Hox-gene transcription is regulated by maternal, gap, and pair-rule transcription factors. The protein encoded by a particular Hox gene controls the organization of cells within the region in which that Hox gene is expressed. For example, a Hox protein can direct

▲ **FIGURE 22-31 Hox-gene phenotypes.** Like other Hox genes, the *Ultrabithorax* (*Ubx*) gene controls the organization of cells within the region in which it is expressed. It normally acts in preventing wing formation, so that normal flies have a single pair of wings. Mutations in Hox genes often lead to the formation of a body part where it does

not normally exist. In the mutant shown here, the loss of *Ubx* function from the third thoracic segment allows wings to form where normally there are only balancer organs called halteres. [From E. B. Lewis, 1978, *Nature* 276:565. Reprinted by permission from *Nature*, copyright 1978, Macmillan Journals Limited.]

▲ **FIGURE 22-32 Relation between Hox gene clusters in *Drosophila* and mammals.** (a) The single *Drosophila* Hox cluster is split into two chromosomal locations; one gene group is the Antennapedia complex and the other is the Bithorax complex. The genes that control head formation are at the 3' end of the cluster (yellow/red shades), those that control formation of the abdomen (yellow/red shades), those that control formation of the abdomen are at the 5' end (blue/green shades), and the ones in-between control thoracic structures (purple), as illustrated in the fly drawing, which shows where the different genes are expressed. (b) The arrangement of genes in the mouse and human Hox gene clusters is similar to that in *Drosophila*, but there are four clusters and each of them is missing some of the set of genes. For example, the class 1 Hox genes of mice and humans are similar to the *lab* gene of *Drosophila*, based on encoded protein sequences. There is a class 1

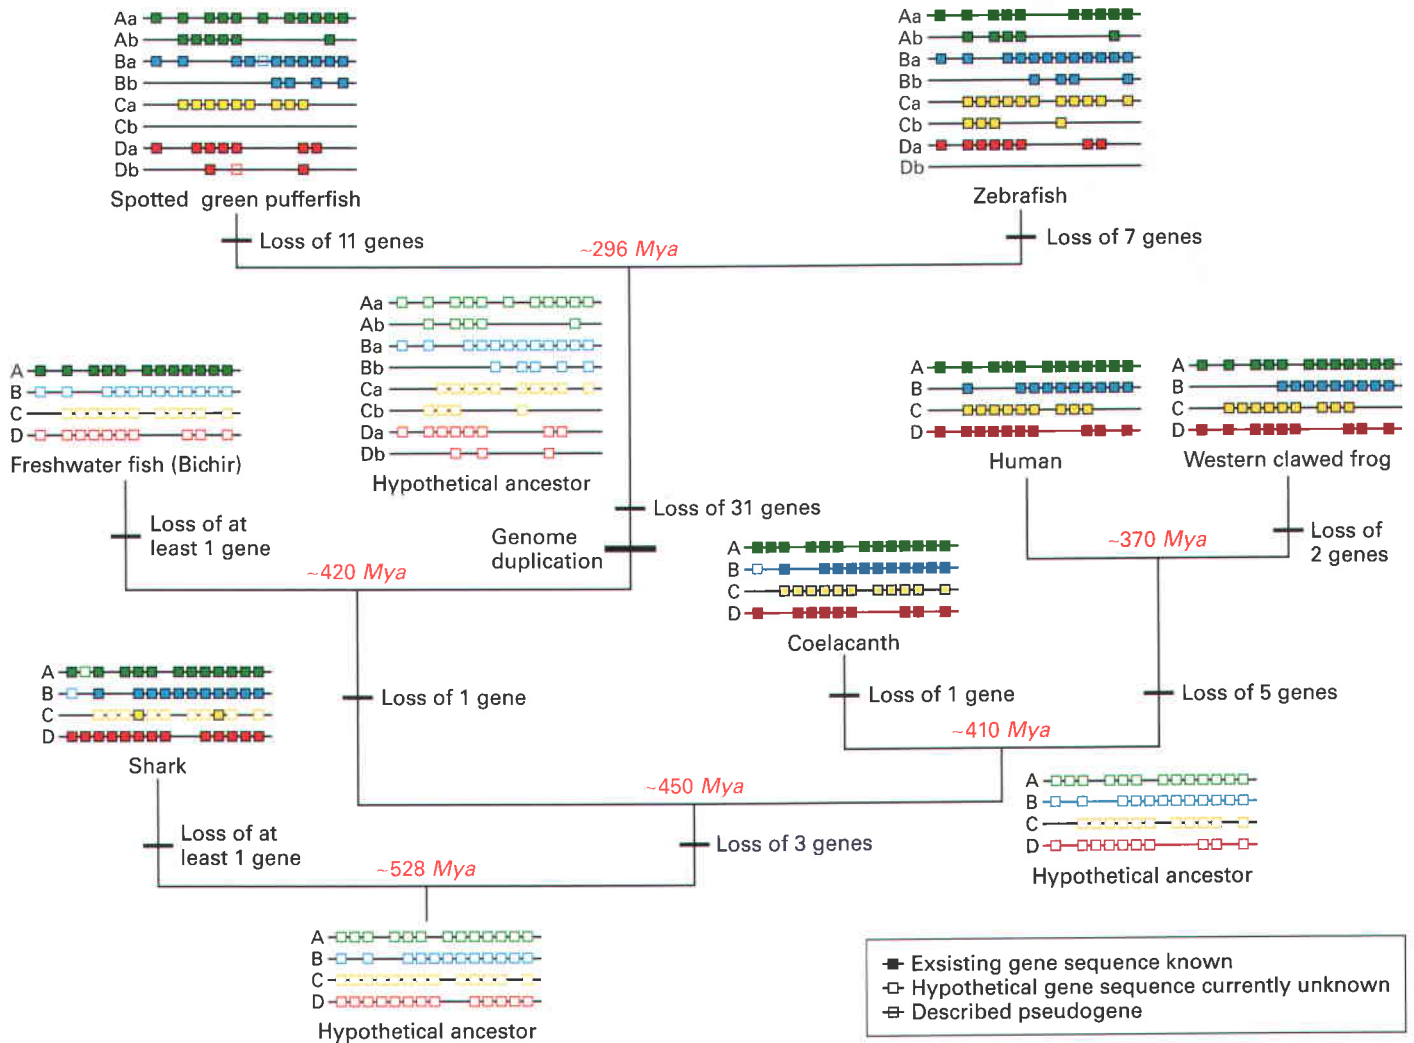

gene in Hox a, b, and d clusters but not in the c cluster. Evidently three is enough. In contrast, the class 4 gene is represented in all of the mammalian clusters. Another difference from insect to mammal is that mammals have “extra” versions of the posterior genes (class 9 and up) that correspond to the *abd*-type genes in flies. The drawings of the fly and mouse embryo indicate where Hox genes are transcribed, from which it can be seen that the order has been preserved during the roughly half billion years since they had a common ancestor. The drawings are a simplification, since in many cases a gene is expressed with a sharp anterior boundary as well as a graded pattern going toward the tail, and expression patterns vary between different tissues. [Adapted from L. Wolpert et al., 2001, *Principles of Development*, 2nd ed., Oxford University Press, Box 4-4a].

or prevent the local production of a secreted signaling protein, cell-surface receptor, or transcription factor that is needed to build an appendage on a particular body segment. *Drosophila* Hox proteins control the transcription of target genes whose encoded proteins determine the diverse morphologies of body segments. Much remains to be learned about how morphology is controlled by these target genes, but some targets encode powerful Wnt and TGF β signals. The association of Hox proteins with their binding sites on DNA is assisted by cofactors that bind to both Hox proteins and DNA, adding specificity and affinity to these interactions.

How about vertebrates? In contrast to flies, which have a single Hox gene cluster, mammals have four copies of the Hox cluster, a–d, located on different chromosomes (Figure 22-32b). Within each cluster, the genes are numbered 1, at the head end, to 13, at the tail end. The different copies of a particular gene (e.g., *Hox4*) in the four clusters are closer to each other in sequence than to Hox genes of another numerical class. Although the mammalian Hox genes are clearly related to the fly Hox genes, there has been an expansion of fly *abd*-type genes in vertebrates (Hox classes 8–13). Within each cluster some genes have been lost, evidently because the other two or three copies are sufficient. Experiments with

mouse “knockouts” missing one or more Hox genes from one numerical class show considerable redundancy among the 39 total genes.

Evolution of Hox Gene Clusters Hox clusters are the most dramatic example of the conservation of gene groupings across a wide range of animals. Their organization is so striking that they serve as useful tools for studying evolution. The single Hox cluster in *Drosophila* is represented four times in mammals (see Figure 22-32). Comparisons of the genome sequences of a variety of vertebrates have revealed that the copies of the Hox clusters are far from perfect. During evolution, some species have lost one or more Hox genes; in other species, Hox genes have become duplicated within a cluster. The transitions between different clusters and losses and gains of individual Hox genes among present-day organisms allow ancestral forms to be deduced (Figure 22-33). For example, in the time since frogs and humans had a common ancestor, about 370 million years ago, frogs have lost Hox genes *b13* and *d12*. As more studies are done of how Hox genes control body morphology, it will be increasingly possible to relate evolutionary changes in Hox genes to pattern formation in the embryos

▲ FIGURE 22-33 Evolution of vertebrate Hox clusters. Genome projects in which all genes are sequenced from different organisms, as well as focused studies of Hox genes, are providing insight into the evolution of the Hox clusters. The Hox clusters shown here in dark green, blue, yellow, and red are based on sequencing of the genomes of the indicated present-day organisms. Comparing sequences from a variety of vertebrates reveals that the copies of the Hox clusters are far from perfect: In some species, one or more genes have been lost, while in others, genes have been duplicated within a cluster. Since the fossil record and studies of DNA sequence conservation have established the relationships between the organisms shown

here, it is possible to deduce the arrangement of Hox genes in hypothetical ancestors (genes in light colors) and reconstruct an outline of the events that happened in the evolution of the Hox clusters. The approximate distances in time (Mya = million years ago) since any pair of species had a common ancestor are indicated in red type. Of course, not all ancestors are represented here, so not every step can be deduced. As more studies are done of how Hox genes control body morphology, it will be increasingly possible to relate evolutionary changes in Hox genes to pattern formation in the embryos they control. [Adapted from S. Hoegg and A. Meyer, 2005, *Trends Genet.* **21**:441.]

they control. This genomics approach to exploring evolution will yield more detailed biological histories as more genomes are sequenced.

Functions of Vertebrate Hox Proteins Vertebrate Hox proteins control the different morphologies of vertebrae, of repeated segments of the hindbrain, and of the digits of the limbs. Mutations affecting some of the most posterior Hox genes in humans cause inherited syndromes that involve polydactyly (extra fingers or toes) and syndactyly (fused fingers or toes). Particular Hox genes are active in many other tissues too. As in flies, mammalian Hox proteins often act in combination to con-

trol target genes, and they use cofactors of the same types used by flies. Mutations affecting some of these cofactors have been implicated in human cancer.

As in flies, Hox-gene expression domains in early vertebrate embryos respond to seemingly invisible boundaries that correspond later to transitions between morphologically distinct repeating body units. Each Hox gene is expressed in some somites but not others (Figure 22-34). They are expressed first in presomitic mesoderm, where they control the morphology of the vertebrae that will form later.

Vertebrae are classified into groups according to their morphology and position along the anterior-posterior axis.

▲ **FIGURE 22-34** Expression of the mouse *Hoxc10* gene in somites. The anterior boundary of *Hoxc10* expression (arrow) is clearly visible in this 9-day-old embryo. [From M. Carapuco et al., 2005, *Genes & Devel.* **19**:2116.]

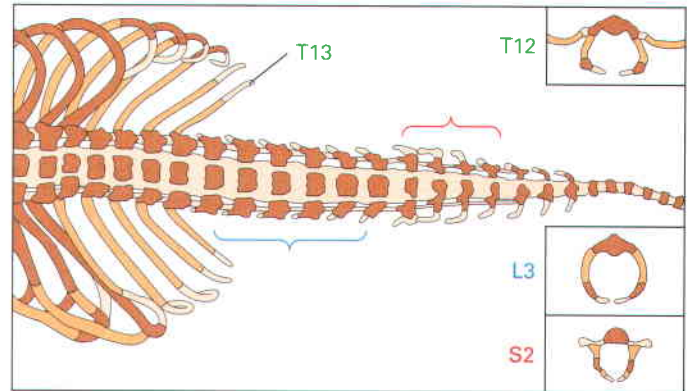

The effects of Hox mutations on vertebral development have been studied with engineered mouse mutants. In one of the most striking experiments, mice were produced that lack functional *Hoxa10*, *Hoxc10*, and *Hoxd10* genes (there is no *Hoxb10*). These mice exhibited a dramatic transformation of vertebral patterns. Lumbar and even sacral vertebrae, which normally have no ribs, developed with varying degrees of partial ribs (Figure 22-35). Probably even more Hox genes would have to be changed for a complete transformation. The inference is that the normal role of Hox10 transcription factors is to prevent rib development.

Hox-Gene Expression Is Maintained by a Variety of Mechanisms

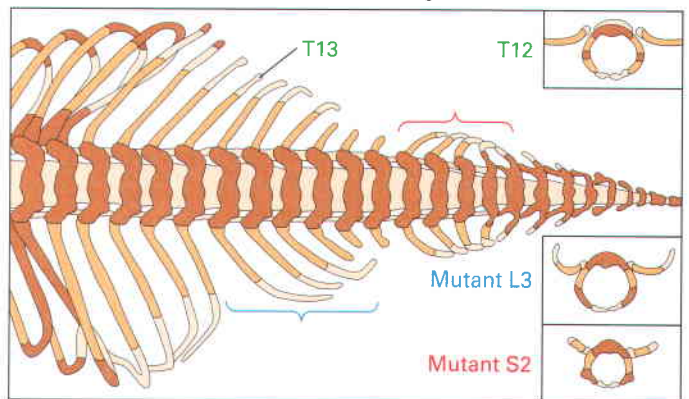

When Hox genes are turned on, their transcription must continue to maintain cell properties in specific locations. As in the case of the pair-rule gene *even-skipped*, the regulatory regions of some Hox genes contain binding sites for their encoded proteins. Thus Hox proteins can help to maintain their own expression through many cell generations using an autoregulatory loop.

Another mechanism for maintaining normal patterns of Hox-gene expression requires proteins that modulate chromatin structure. These proteins are encoded by two classes of genes referred to as the Trithorax group and Polycomb group. The pattern of Hox-gene expression is initially normal in Polycomb-group mutants, but eventually Hox-gene transcription is derepressed in places where the genes should be inactive. The result is multiple homeotic transformations, indicating that the normal function of Polycomb proteins is to keep Hox genes in a transcriptionally inactive state. The results of immunohistological and biochemical studies have shown that Polycomb proteins bind to multiple chromosomal locations and form large complexes containing different proteins of the Polycomb group. The current view is that the transient repression of genes set up by patterning proteins earlier in development is “locked in” by Polycomb proteins. This stable Polycomb-dependent repression may result from the ability of these proteins to assemble inactive chromatin structures (Chapter 7). Polycomb complexes contain many proteins,

Wild type

Hox10 mutant (lacks all *Hox10a*, *c*, and *d* genes)

▲ **EXPERIMENTAL FIGURE 22-35** *Hox10* genes regulate vertebral shape. Separate knockout mice were constructed, each lacking a portion of the *Hox10 a*, *c*, or *d* gene. Each of these genes is on a different chromosome. In each case, heterozygous mice survived because they have a second, wild-type, copy of the gene. The mice were crossed to construct a strain heterozygous for mutations at all three genetic loci. Crossing these mice together generated some homozygous mutant embryos lacking both copies of all three *Hox10* genes. Skeletons from 18.5 day mutant embryos and wild-type embryos were isolated and stained to reveal the details of the skeletons. These top-view and cross-sectional diagrams, based on the stained skeletons, illustrate the results. In wild-type mice, the thoracic (T) vertebrae have ribs, with the most posterior rib on T13. Lumbar (L) vertebrae (blue bracket) and sacral (S) vertebrae (red bracket) do not have ribs. Mutants that are homozygous for all three *Hox10* genes have ribs on lumbar vertebrae (e.g., L3) that would normally have been ribless, and even on some sacral ribs (e.g., S2). The insets show cross sections of different vertebrae and ribs to reveal their shapes in that dimension. From these results we can infer that Hox10 proteins are normally required to suppress rib formation on the developing lumbar and sacral vertebrae. Since the *Hox10* genes are normally expressed in this region of the embryo, this conclusion makes sense. If any one *Hox10* gene is functioning, the extra ribs are not seen, or only rarely seen, so the *Hox10* genes have at least partially redundant functions. [Adapted from D. M. Wellik and M. R. Capecchi, 2003, *Science* **301**:363.]

including histone deacetylases, and appear to inactivate transcription by modifying histones to promote gene silencing.

Whereas Polycomb proteins repress expression of certain Hox genes, proteins encoded by the Trithorax group of genes are necessary for maintaining expression of Hox genes. Like Polycomb proteins, Trithorax proteins bind to multiple chromosomal sites and form large multiprotein complexes, some with a mass of $\approx 2 \times 10^6$ Da, about half the size of a ribosome. Some Trithorax-group proteins are homologous to the yeast SWI/SNF proteins, which are crucial for transcriptional activation of many yeast genes. Trithorax proteins stimulate gene expression by selectively remodeling the chromatin structure of certain loci to a transcriptionally active form (see Figure 7-43). The core of each complex is an ATPase, often of the Brm class of proteins. There is evidence that many or most genes require such complexes for transcription to take place.

Many regulators of Hox-gene expression have been implicated in leukemia. Chromosomal translocations that fuse the genes encoding these regulators to novel sequences, sometimes causing a gene encoding a chimeric protein to form, are frequently found in leukemia patients. Such fusions, for instance, can create oncogenes that cause white blood cells to grow uncontrollably (see Figure 25-20). Hox genes are active in blood cells, though Hox functions in those cells are incompletely understood.

Homeotic genes—that is, genes like the Hox genes that control development of whole parts of the body—are also important in plant development, as we shall see now. Again the homeotic genes superimpose a set of variations on an underlying repeat pattern.

Flower Development Requires Spatially Regulated Production of Transcription Factors

 It may seem a long jump from animal segmentation to plants, but in terms of the molecules that control pattern formation, many principles are similar. Like vertebrae or insect segments, flowers have repeating parts. The basic mechanisms controlling development in plants are much like those in *Drosophila*: differential production of transcription factors, controlled in space and time, specifies cell identities. Our understanding of cell-identity control in plants benefited greatly from the choice of *Arabidopsis thaliana* as a model organism. This plant has many of the same advantages as flies and worms for use as a model system: It is easy to grow, mutants can be obtained, and transgenic organisms can be made. We will focus on certain transcription-control mechanisms regulating the formation of cell identity in flowers. These mechanisms are strikingly similar to those controlling cell-type and anterior-posterior regional specification in yeast and animals. ■

Floral Organs A flower comprises four different organs called sepals, petals, stamens, and carpels, which are arranged in concentric circles called whorls. Whorl 1 is the outermost; whorl 4, the innermost. *Arabidopsis* has a complete set of floral organs, including four sepals in whorl 1, four petals in whorl 2,

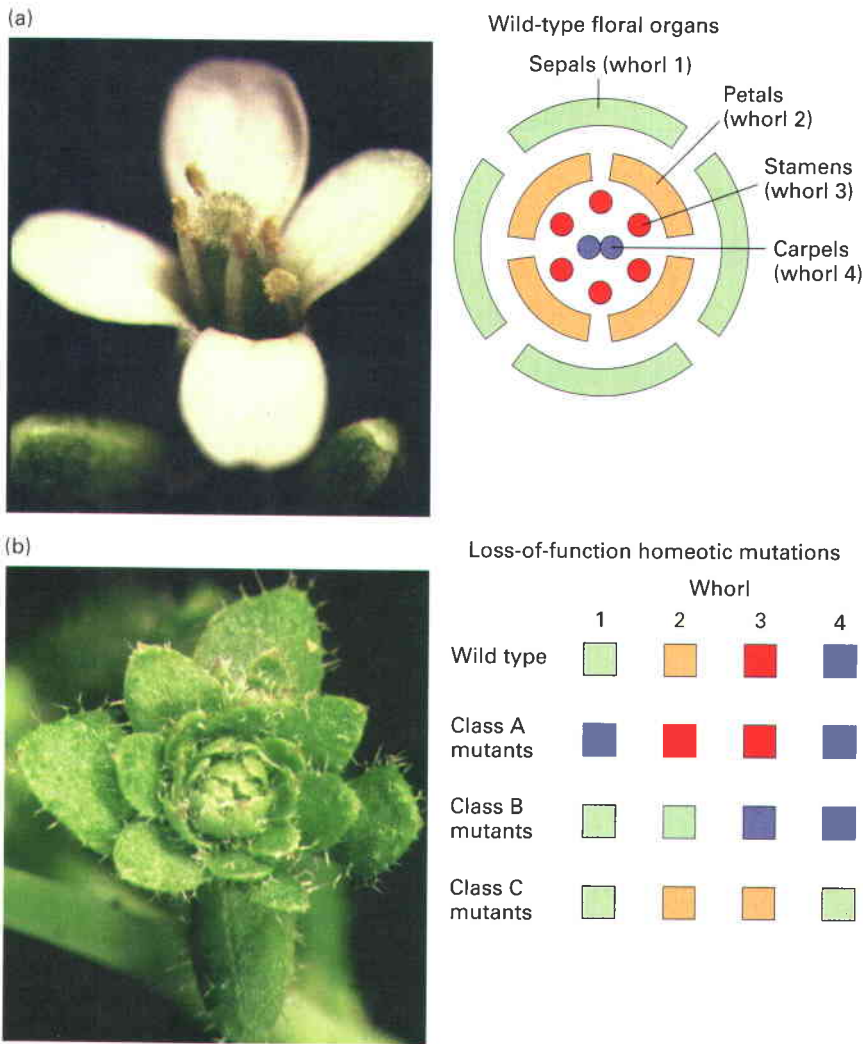

six stamens in whorl 3, and two carpels containing ovaries in whorl 4 (Figure 22-36a). These organs grow from a collection of undifferentiated, morphologically indistinguishable cells called the floral **meristem**. As cells within the center of the floral meristem divide, four concentric rings of primordia form sequentially. The outer-ring primordium, which gives rise to the sepals, forms first, followed by the primordium giving rise to the petals, then the stamen and carpel primordia.

Floral Organ–Identity Genes Genetic studies have shown that normal flower development requires three classes of *floral organ–identity genes*, designated A, B, and C genes. Mutations in these genes produce phenotypes equivalent to those associated with homeotic mutations in flies and mammals; that is, one part of the body is replaced by another. In plants lacking all A, B, and C function, the floral organs develop as leaves (Figure 22-36b, *left*).

The loss-of-function mutations that led to the identification of the A, B, and C gene classes are summarized in Figure 22-36b (*right*). On the basis of the various homeotic phenotypes observed, scientists proposed a model to explain how the three classes of genes control floral-organ identity. According to this ABC model for specifying floral organs, class A genes specify sepal identity in whorl 1 and do not require either class B or class C genes to do so. Similarly, class C genes specify carpel identity in whorl 4 and, again, do so independently of class A and B genes. In contrast with these structures, which are specified by only a single class of genes, the petals in whorl 2 are specified by class A and B genes, and the stamens in whorl 3 are specified by class B and C genes. To account for the observed effects of removing A genes or C genes, the model also postulates that A genes repress C genes in whorls 1 and 2 and, conversely, C genes repress A genes in whorls 3 and 4.

To determine if the actual expression patterns of class A, B, and C genes are consistent with this model, researchers cloned these genes and assessed the expression patterns of their mRNAs in the four whorls in wild-type *Arabidopsis* plants and in loss-of-function mutants (Figure 22-37a, b). Consistent with the ABC model, A genes are expressed in whorls 1 and 2, B genes in whorls 2 and 3, and C genes in whorls 3 and 4. Furthermore, in class A mutants, class C genes are also expressed in organ primordia of whorls 1 and 2; similarly, in class C mutants, class A genes are also expressed in whorls 3 and 4. These findings are consistent with the homeotic transformations observed in these mutants.

To test whether these patterns of expression are functionally important, scientists produced transgenic *Arabidopsis* plants in which floral organ–identity genes were expressed in inappropriate whorls. For instance, the introduction of a transgene carrying class B genes linked to an A-class promoter leads to the ubiquitous expression of class B genes in all whorls (Figure 22-37c). In such transgenics, whorl 1, now under the control of class A and B genes, develops into petals instead of sepals; likewise, whorl 4, under the control of both class B and class C genes, gives rise to stamens instead of carpels. These results support the functional importance of the ABC model for specifying floral identity.

◀ **FIGURE 22-36 Floral organs and the effects of mutations in organ-identity genes.** (a) Flowers of wild-type *Arabidopsis thaliana* have four sepals in whorl 1, four petals in whorl 2, six stamens in whorl 3, and two carpels in whorl 4. The floral organs are found in concentric whorls as diagrammed at right. (b) In *Arabidopsis* with mutations in all three classes of floral organ-identity genes, the four floral organs are transformed into leaf-like structures (left). Phenotypic analysis of mutants identified three classes of genes that control specification of floral organs in *Arabidopsis* (right). Class A mutations affect organ identity in whorls 1 and 2: sepals (green) become carpels (purple) and petals (orange) become stamens (red). Class B mutations cause transformation of whorls 2 and 3: petals become sepals and stamens become carpels. In class C mutations, whorls 3 and 4 are transformed: stamens become petals and carpels become sepals. [See D. Wiegand and E. M. Meyerowitz, 1994, *Cell* **78**:203.]

Sequencing of floral organ-identity genes revealed that many encode proteins belonging to the *MADS* family of transcription factors, which form homo- and hetero-dimers. Thus floral-organ identity may be specified by a combinatorial mechanism in which differences in the activities of different

homo- and heterodimeric forms of various A, B, and C proteins regulate the expression of subordinate downstream genes necessary for the formation of the different cell types in each organ. Other MADS transcription factors function in cell-type specification in yeast and muscle (Chapter 21).

▲ **EXPERIMENTAL FIGURE 22-37 Expression patterns of class A, B, and C genes support the ABC model of floral organ specification.** Depicted here are the observed expression patterns of the floral organ-identity genes in wild-type, mutant, and transgenic *Arabidopsis*. Colored bars represent the A, B, and C mRNAs in each

whorl (W1, W2, W3, W4). The observed floral organ in each whorl is indicated as follows: sepal = se; petals = pe; stamens = st; and carpels = ca. See text for discussion. [See D. Wiegand and E. M. Meyerowitz, 1994, *Cell* **78**:203, and B. A. Krizek and E. M. Meyerowitz, 1996, *Development* **122**:11.]

KEY CONCEPTS OF SECTION 22.4

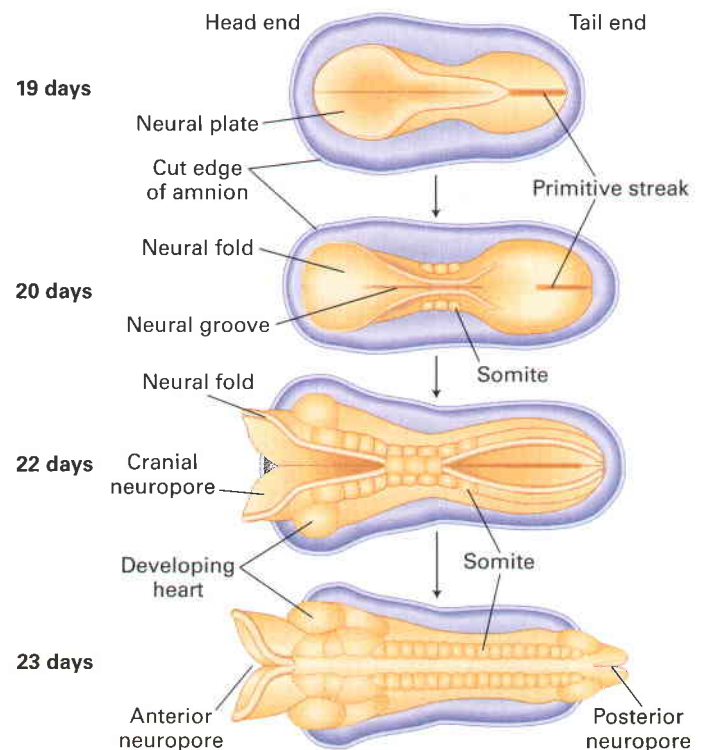

Control of Body Segmentation: Themes and Variations in Insects and Vertebrates

- Segmentation is a common feature of pattern formation in many animals, as indicated by our vertebrae and insect body segments.
- In *Drosophila*, early development gives rise to an embryo with about 6000 cells in a sheet on the surface (see 22-21). Because the early embryo is a syncytium, both transcription factors and secreted proteins can function as graded regulators, or morphogens.
- One system of genes and proteins controls anterior-posterior organization of the fly embryo; another controls dorsal-ventral patterning. Thus a cell in any particular position in the embryo integrates two types of informative signals. RNA and protein placed asymmetrically in the oocyte by the mother gives rise to the initial asymmetries in the embryo (see Figures 22-23 and 22-24).
- Three classes of genes act sequentially to subdivide the fly embryo into segments along the anterior-posterior axis. Gap genes are expressed first, then pair-rule genes, and finally segment-polarity genes (see Figure 22-27). The gap and pair-rule genes encode transcription factors; segment-polarity genes encode components of the Hedgehog and Wnt signaling pathways.
- The striped patterns of expression of pair-rule genes such as *even-skipped* are controlled by enhancers that activate transcription when bound by specific combinations of gap-gene proteins (see Figure 22-28). Each stripe forms where the proper combination of gap proteins occurs, in a certain position along the anterior-posterior axis. Similarly pair-rule proteins combine to regulate segment-polarity genes.
- Vertebrate segmentation begins with the formation of repeating blocks of mesoderm called somites, first near the head and then sequentially in more posterior regions (see Figure 22-29).
- In vertebrates, somite formation is controlled by the cyclical expression of genes such as *hes7* along the anterior-posterior axis. This pattern of gene expression depends on steady FGF signals from the developing tail and negative autoregulation of the genes involved in somite formation (see Figure 22-30).
- In flies, humans, and many other animals, the different patterns of segments along the anterior-posterior axis are controlled by Hox genes (see Figure 22-32). For example, the differences in the shapes of vertebrae are regulated by Hox-gene products.
- Hox genes encode transcription factors that regulate batteries of genes that in turn control cell and tissue morphology. Hox genes act in many tissue types; their expression patterns are maintained by the action of negative- and positive-acting chromatin proteins. Mutations in Hox genes cause body parts to form in the wrong places.

- The shapes and patterns of flower petals, stamens, carpals, and sepals are controlled by the combined actions of MADS transcription factors encoded by three classes of *floral-organ identity genes*. In plants with mutations in all three classes, leaves rather than flowers develop (see Figure 22-36b), a transformation reminiscent of the Hox mutations in animals.

22.5 Cell-Type Specification in Early Neural Development

By the end of gastrulation, the animal embryo has three germ layers, and its three axes—head to tail, front to back, and left to right—are easily detectable. The ectoderm and endoderm are largely epithelial sheets, sandwiching a mass of more loose-knit mesenchymal mesoderm cells. Now the embryo has to make a nervous system. To do so, the embryo starts folding along the central axis of posterior ectoderm, a process called **neurulation** (Figure 22-38).

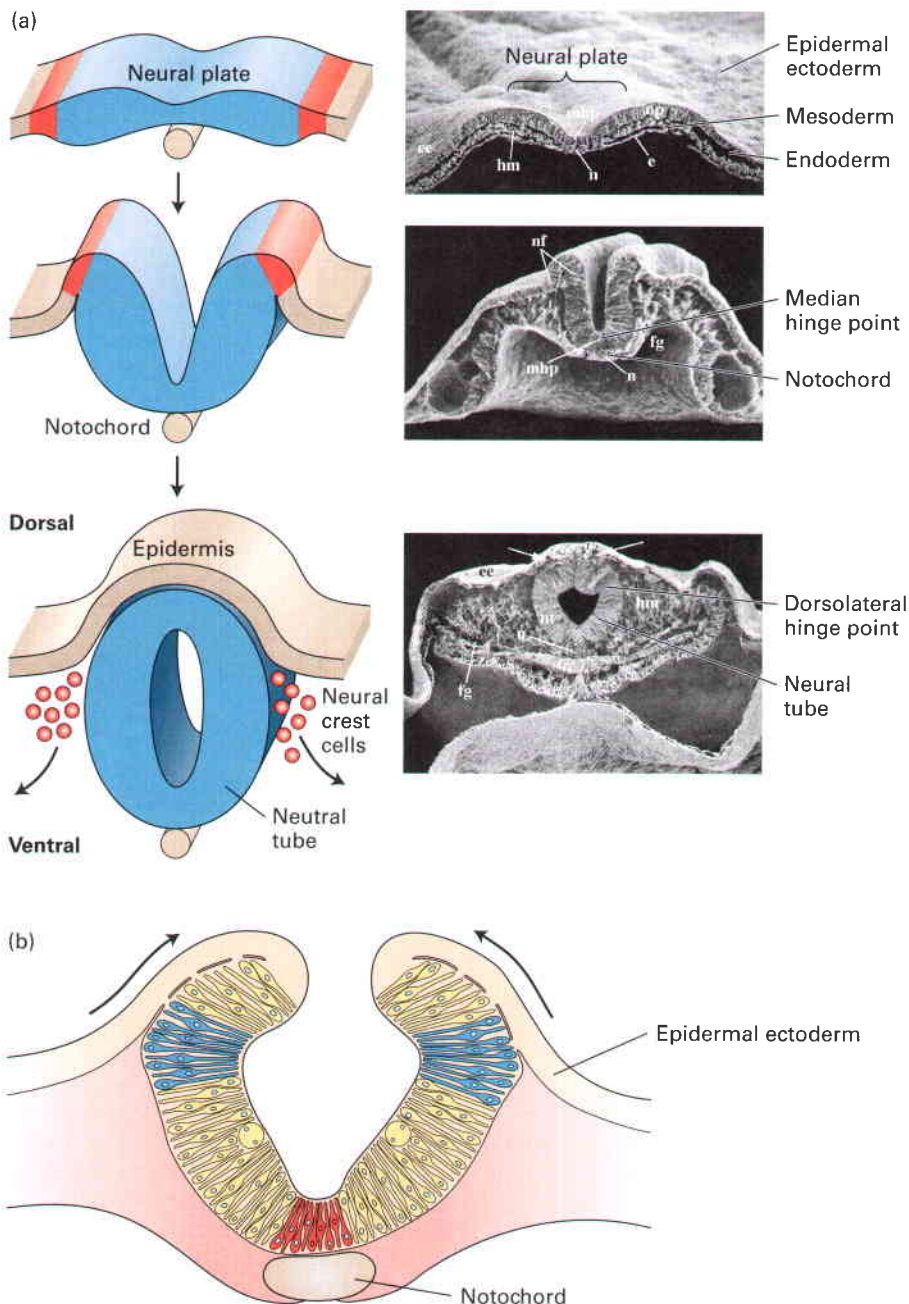

▲ **FIGURE 22-38 Neurulation in the human embryo.** In these drawings, the amniotic membrane has been “removed” to reveal the embryo, called the neurula at this stage. Folding of the ectoderm destined to become neural tissue begins in the center of the embryo at about 21 days of fetal development and proceeds toward both ends, forming the neural tube. At the same time, somites are progressively forming in the mesoderm. The cranial neuropore at the head end of the neural tube closes at about day 24 of human fetal development; the neural tube is completed at the tail end (caudal neuropore) on day 26. Defects in neural tube closure lead to a variety of serious and all-too-frequent birth defects, including spina bifida. [Adapted from W. J. Larsen, 1997, *Human Embryology*, 2nd ed., Churchill-Livingstone, Figure 4-9.]

Neurulation Begins Formation of the Brain and Spinal Cord

Signals that are still poorly understood designate cells along the midline as prospective neural tissue. The best evidence to date, from amphibians and mice, shows that BMP4 prevents neural induction, whereas antagonists of BMP4 such as Chordin, Noggin, and Cerberus can induce neural cell fates by opposing BMP4. Wnt signaling also may induce neural fates by acting earlier and preventing BMP4 expression in certain cells. Whatever the exact series of regulatory events, the prospective neural cells are located in the sheet of ectodermal cells along with flanking cells that will eventually form epidermis. Along what will become the spine, a portion of the ectodermal sheet (the neural plate) folds inward to make a U-shaped canyon (Figure 22-39a). This is the beginning of the *neural tube*. Folding of the

neural plate results from highly organized changes in the cytoskeleton of participating cells. Rearrangement of microfilaments in some neural plate cells make the cells wedge-shaped, causing the ectodermal sheet to fold (Figure 22-39b). This is a clear example of how changes in individual cells can contribute to the organized shape changes of large embryonic structures. Each cell has to have enough information to contribute usefully to forming the tissue as a whole.

Neural tube formation also depends on **micro RNAs (miRNAs)**, short RNAs that can influence gene expression by controlling mRNA function or inhibiting translation (see Figures 8-26 and 8-27). Evidence for the involvement of miRNAs in neurulation came from studies with zebrafish in which Dicer, the enzyme that processes micro RNAs, was mutated, thus effectively eliminating all miRNA activity. The resulting embryos

◀ **FIGURE 22-39** Neurulation in the chick.

(a) Drawings on the left show the ectoderm initially divided into prospective neural (blue and red) and epidermal (tan) cells. The neural primordium (neural plate) begins to fold, and eventually the neural folds fuse to make the neural tube. Part of the underlying mesoderm undergoes a mesenchymal-epithelial transition to form the rod-like notochord (from which the term *chordates* is derived). A population of cells (red) near the site of fusion undergo an epithelial-mesenchymal transition and migrate away from the neural tube. These neural crest cells will contribute to heart valves, most of the facial bones, peripheral nervous system, and melanocytes that form the pigment in skin. During neurulation, the epidermis loses its continuity with the neural tissue and fuses above it. Scanning electron micrographs show chick embryos at the same stages of neurulation. (b) In the cooperative (hinge-point) model of neurulation, microfilament rearrangements cause wedging of neuroepithelial cells within two dorsolateral hinge points (blue) and single median hinge point (red). Arrows indicate mediolateral expansion of the epidermal ectoderm. [Part (a) drawings adapted from L. Wolpert et al., 2001, *Principles of Development*, 2nd ed., Oxford Press, Figure 11-10; micrographs courtesy of J. F. Colas and G. C. Schoenwolf, Part (b) adapted from J. F. Colas and G. C. Schoenwolf, 2001, *Devel. Dyn.*, **221**:117.]

had proper axis formation but failed to undergo neurulation. To demonstrate that miRNAs, and not some other molecule affected by Dicer, are responsible for the problem, scientists attempted to rescue the mutant fish embryos by injecting them with a prominent class of preformed miRNA duplexes. This succeeded to a remarkable degree, restoring much of the defective neural development. It will be fascinating to learn in the future how miRNAs control neural tube morphogenesis.

Signal Gradients and Transcription Factors Specify Cell Types in the Neural Tube and Somites

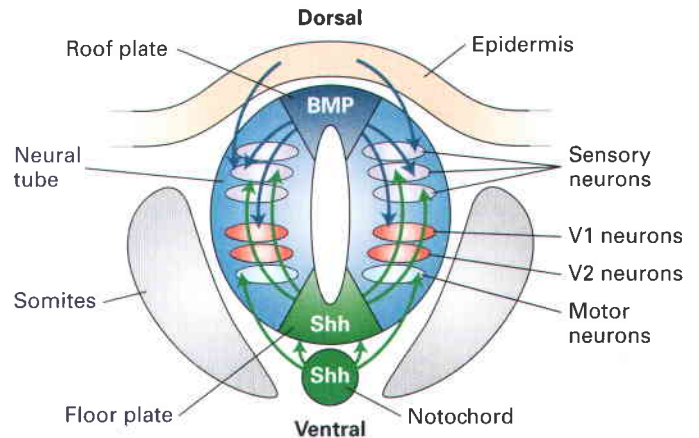

As we've seen already, developmental signals can act in relay fashion, a sort of bucket brigade in which each cell receives one signal and passes on another, or in graded fashion, in which different concentrations of one signal induce different cell fates (see Figure 22-13). Graded signals, or morphogens, are important in specifying cell fates in different parts of the neural tube: motor neurons in the ventral part, a variety of interneurons in the lateral parts, and sensory neurons in the dorsal part. The different cell types can be distinguished, prior to morphological differentiation, by the proteins that they produce.

Graded concentrations of Sonic hedgehog (Shh), a vertebrate equivalent of *Drosophila* Hedgehog, determine the fates of at least four cell types in the chick ventral neural tube. These cells are found at different positions along the dorsoventral axis in the following order from ventral to dorsal: floor-plate cells, motor neurons, V2 interneurons, and V1 interneurons. During development, Shh is initially produced at high levels in the notochord, which directly contacts the ventral-most region of the neural tube (Figure 22-40a). The Shh from the notochord induces the most ventral neural-tube cells to form floor-plate cells, a type of non-neuronal glial cell (Chapter 23). Floor-plate cells also produce Shh, forming a Shh-signaling center in the ventral-most region of the neural tube. Antibodies to Shh protein block the formation of the different ventral neural-tube cells in the chick, and these cell types fail to form in mice homozygous for mutations in the *Sonic hedgehog* (*Shh*) gene.

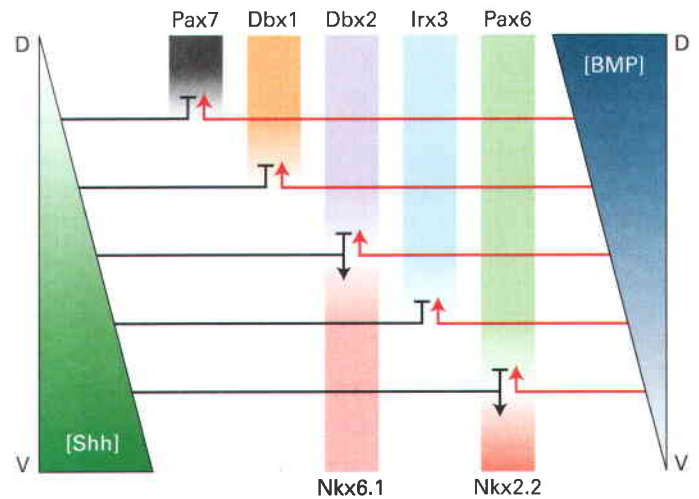

To determine whether Shh-triggered induction of ventral neural-tube cells is through a graded or a relay mechanism, scientists added different concentrations of Shh to chick neural-tube explants. In the absence of Shh, no ventral cells formed. In the presence of very high concentrations of Shh, floor-plate cells formed; whereas, at a slightly lower concentration, motor neurons formed. When the level of Shh was decreased another twofold, only V2 neurons formed. And, finally, only V1 neurons developed when the Shh concentration was decreased another twofold. These data strongly suggest that in the developing neural tube different cell types are formed in response to a ventral → dorsal gradient of Shh, though exactly when in development the signal has its impact is unknown. The accumulating evidence for gradients does not rule out additional relay signals that may yet be discovered.

Cell fates in the dorsal region of the neural tube are determined by BMP proteins (e.g., BMP4 and BMP7), which belong to the TGFβ family. Recall that TGFβ-type signals

(a) Graded induction of different cell types in the neural tube by Shh and BMP signals

(b) Responses of neural-tube cells to graded Shh and BMP signals along dorsal-ventral axis

▲ FIGURE 22-40 Regulation of neural-cell fate in vertebrates.

(a) Sonic hedgehog (Shh) secreted by cells in the notochord induces floor-plate development. The floor plate, in turn, produces Shh, which forms a ventral → dorsal gradient that induces additional cell fates. In the dorsal region, BMP proteins (TGFβ-type signals) secreted from overlying ectoderm cells and subsequently from roof plate cells. (b) The relative concentrations of Shh and BMP are indicated by the colored gradients. Cell fates in the neural tube can be detected by the differential production of all the transcription factors shown between the gradients. High to moderate levels of Shh induce expression of the *Nkx2.2* and *Nkx6.1* genes (↓) but block production of the five transcription factors indicated at the top (↑). Even low levels of Shh can block expression of *Dbx1* and *Pax7*, both genes whose expression is promoted by BMP signals coming from cells in the dorsal neural tube. The border between *Pax6* and *Nkx2.2*, and between *Dbx2* and *Nkx6.1*, is further sharpened by mutually repressive interactions; each protein turns off the gene encoding the other protein. The outcome of all this is a set of different cell fates (e.g., motor neurons or sensory neurons) along the dorsal-ventral axis. Each cell type contains a unique blend of transcription factors, which presumably control expression of many other genes that confer distinctive properties on cells that type. [See T. M. Jessell, 2000, *Nature Rev. Genet.* 1:20.]

and their antagonists are critical in determining dorsal cell fates in early frog embryos. A *Drosophila* TGF β signal called Dpp also functions in determining dorsal cell fates in early fly embryos. Indeed, TGF β signaling appears to be an evolutionarily ancient regulator of dorsoventral patterning. In vertebrate embryos, BMP proteins secreted from ectoderm cells overlying the dorsal side of the neural tube promote the formation of dorsal cells such as sensory neurons (see Figure 22-40a). Thus cells in the neural tube sense multiple signals that originate at opposite positions on the dorsoventral axis. By integrating the signals from both origins, each cell embarks on a particular course of differentiation.

The gradients of Shh and TGF β spreading out from the ventral and dorsal sides of the neural tube activate or repress the production of particular transcription factors in neural-tube cells at different positions along the dorsal-ventral axis (Figure 22-40b). When these transcription factors are first made, the boundaries between them are fuzzy, but some of the boundaries sharpen due to mutually repressive cross-regulation.

Similar mechanisms determine cell fates in the somites, which give rise to body wall muscle (*myotome*), the inner layer of skin called the dermis (*dermatome*), and the vertebrae (*sclerotome*). These different cell fates are induced by signals from surrounding tissues. For instance, Shh coming from the notochord induces sclerotome. Thus the same signal, Shh, induces motor neurons in the neural tube and bone primordia in the somites. The receiving cells are pre-programmed to respond in distinct ways to the same inducer depending on their prior history. Somites also receive signals from other directions, such as Wnt from the dorsal neural tube, that induce different subsets of cells.

Most Neurons in the Brain Arise in the Innermost Neural Tube and Migrate Outward

The cortex of the brain is a thin sheet of cells organized into half a dozen layers. This portion of our anatomy—required for the most-advanced thinking abilities—is the source of our greatest pride and feelings of superiority, for better or worse, over other living things. Development of the neural tube, which is initially a single cell layer thick, into a brain requires both the generation of vast numbers of new, progenitor cells from stem cells and the organization of those new cells into layers.

The new cells form mostly in the *subventricular zone*, the inner lining of the neural tube lying closest to the ventricles, which are the fluid-filled cavities inside the brain that arise from the interior of the neural tube. Cells take up their final positions in a simple inside-out order, forming the innermost layer first and then, progressively, the outer ones (see Figure 21-12). Thus neurons born late have to migrate past the older cells that have already taken up their stations. The migration of some cells involves interactions with radial glia, support cells that elongate to span the entire distance from the subventricular zone to the outer layer of the cortex. In addition some cells undergo remarkable tangential migration at right angles to the ventricle-to-surface plane.

Scientists have used time-lapse microscopy to observe the behaviors of migrating neurons. Their movement is not

smooth or continuous. Instead, the cells move vigorously for a time, pause and extend processes in what appears to be a testing of the waters, and then resume motion in either the original direction or another. In some cases neurons seem to move over each other; in other cases they follow the processes of glia cells. Migrating cells are responding to a wide variety of guidance cues in the form of surface molecules and secreted signals, while internally each cell undergoes dramatic shape changes.

Once neurons reach their final destinations, and often while they are in transit, they form long processes to communicate with other cells: the **dendrites**, which receive signals, and the **axons**, which transmit signals, sometimes over distances greater than a meter. We will discuss how the correct wiring pattern is built, to the extent that it is understood, in Chapter 23.

Lateral Inhibition Mediated by Notch Signaling Causes Early Neural Cells to Become Different

The development of the nervous system provides examples of an important general mechanism for ensuring that all necessary structures are built, but not in excessive numbers. This mechanism called **lateral inhibition**, consists in essence of a cell communicating to surrounding cells “I am doing this, so you should make something else.” Adjacent cells with equivalent or near-equivalent potential are in this way directed toward distinct fates. Genetic analyses of *Drosophila* neural development first revealed the role of the highly conserved Notch/Delta pathway in lateral inhibition. The *Drosophila* proteins Notch and Delta are the prototype receptor and ligand, respectively, in this signaling pathway. Both proteins are large transmembrane proteins whose extracellular domains contain multiple EGF-like repeats and binding sites for the other protein. Although Delta is cleaved to make an apparently soluble version of its extracellular domain, findings from studies with genetically mosaic *Drosophila* have shown that the Delta signal reaches only adjacent cells.

Interaction between Delta and Notch triggers the proteolytic cleavage of Notch, releasing its cytosolic segment, which translocates to the nucleus and regulates the transcription of specific target genes (see Figure 16-36). In particular, Notch signaling activates the transcription of *Notch* itself and represses the transcription of *Delta*, thereby intensifying the difference between the interacting cells (Figure 22-41a). Notch-mediated signaling can give rise to a sharp boundary between two cell populations or can single out one cell from a cluster of cells (Figure 22-41b). Notch signaling controls cell fates in most tissues and has consequences for differentiation, proliferation, the creation of cell asymmetry, and apoptosis. Here we describe two examples of Notch signaling in cell-fate determination.

Loss-of-function mutations in the *Notch* or *Delta* genes produce a wide spectrum of phenotypes in *Drosophila*. One consequence of such mutations in either gene is an increase in the number of neuroblasts in the central nervous system. In *Drosophila* embryogenesis, a sheet of ectoderm cells becomes divided into two populations of cells: those that move inside the embryo develop into neuroblasts, which give rise to neurons; those that remain external form the epidermis and cuticle (see

▲ **FIGURE 22-41 Amplification of an initial bias to create different cell types by Notch-mediated lateral inhibition.** (a) A difference between two initially equivalent cells may arise randomly (left). Alternatively, interacting cells may have an intrinsic bias (center) or an extrinsic bias (right). For instance, cells that have received different proteins in an asymmetric cell division will be intrinsically biased; those that have received different signals (orange) will be extrinsically biased. Regardless of how the small initial bias arises, Notch becomes predominant in one of the two cells, promoting its own expression and repressing production of its ligand Delta in that cell. In the other cell, production of Delta predominates. The outcome is reinforcement of the small initial difference. (b) Notch-mediated lateral inhibition may create a sharp boundary in an initial field of cells, such as along the edge of the developing *Drosophila* wing, or distinguish a central cell from a surrounding cluster of cells, as in neural precursor establishment. [Adapted from S. Artavanis-Tsakonas et al., 1999, *Science* 284:770.]

Figure 21-29). As some of the cells enlarge and then loosen from the ectodermal sheet to become neuroblasts, they signal to surrounding cells to prevent their neighbors from becoming neuroblasts—a case of lateral inhibition. Notch/Delta signaling is used for this inhibition; in embryos lacking the Notch receptor or its ligand, all the ectoderm precursor cells become neural.

The role of Notch signaling in specifying neural cell fates has been studied extensively in the developing *Drosophila* peripheral nervous system. In flies, various sensory organs arise from proneural cell clusters, which produce bHLH transcription factors, such as Achaete and Scute, that promote neural cell fates. In normal development, one cell within a proneural cluster is somehow anointed to become a *sensory organ precursor* (SOP).

cursor (SOP). In the other cells of a cluster, Notch signaling leads to the repression of proneural genes, and so the neural fate is inhibited; these nonselected cells give rise to epidermis (Figure 22-42). Temperature-sensitive mutations that cause functional loss of either Notch or Delta lead to the development of additional SOPs from a proneural cluster. In contrast, in developing flies that produce a constitutively active form of Notch (i.e., active in the absence of a ligand), all the cells in a proneural cluster develop into epidermal cells.

To assess the role of the Notch pathway during primary neurogenesis in vertebrates, scientists injected mRNA encoding different forms of Notch and Delta into *Xenopus* embryos. Injection of mRNA encoding the constitutively active cytosolic segment of Notch inhibited the formation of neurons. In contrast, injection of mRNA encoding an altered form of Delta that prevents Notch activation led to

▲ **FIGURE 22-42 Role of Notch-mediated lateral inhibition in formation of sensory organ precursors (SOPs) in *Drosophila*.**

(a) Extracellular signaling molecules and transcription factors, encoded by early-patterning genes, control the precise spatiotemporal pattern of proneural bHLH proteins such as Achaete and Scute (yellow). Most cells within the field express Emc (orange), a related protein that antagonizes Achaete and Scute. A small group of cells, a proneural cluster, produce proneural bHLH proteins. The region of a proneural cluster from which an SOP will form expresses lower levels of Emc, giving these cells a bias toward SOP formation. Interactions among these cells, mediated by Notch signaling, leads to accumulation of Notch-regulated *E(spl)* repressor proteins in neighboring cells (blue), restricting SOP formation to a single cell (green). (b) Initially, *achaete* (*ac*) and other proneural genes are transcribed in all the cells within a

proneural cluster, as are *Notch* and *Delta*. Achaete and other proneural bHLH proteins promote expression of *Delta*. When one cell at random begins to produce slightly more Achaete (left), its production of Delta increases, leading to stronger Notch signaling in all its neighboring cells (right). In the receiving cells, the Notch signaling pathway activates a transcription factor designated Su(H), which in turn stimulates expression of *E(spl)* genes. *E(spl)* expression stays low in the high-Delta (left) cell, allowing a neural, i.e. SOP, fate. In the right cell, the *E(spl)* proteins specifically repress transcription of *ac* and other proneural genes. The resulting decrease in Achaete leads to a decrease in Delta, thus amplifying the initial random difference among the cells. As a consequence of these interactions and others, one cell of a proneural cluster is selected as a SOP; all the others lose their neural potential and develop into epidermal cells.

the formation of too many neurons. These findings indicate that in vertebrates, as in *Drosophila*, lateral inhibition mediated by Notch signaling controls neural precursor cell fates. Similarly in the nematode *Caenorhabditis elegans*, Notch signaling is used during vulva development to form distinct adjacent cell types by lateral inhibition. The Notch signaling pathway is used during the formation of many organs and tissues, but not always for lateral inhibition.

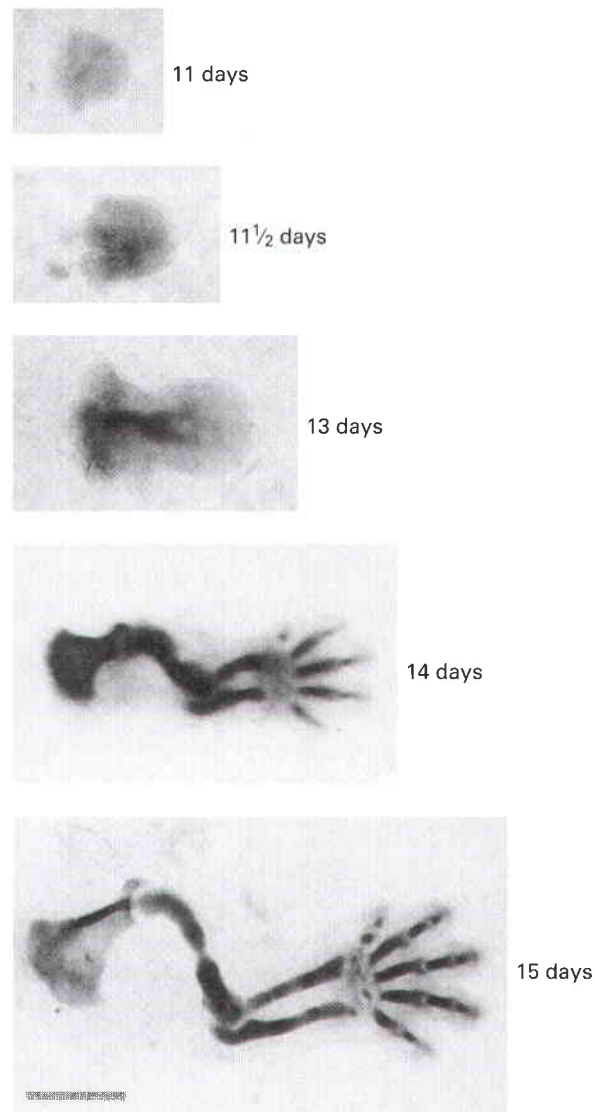

KEY CONCEPTS OF SECTION 22.5

Cell-Type Specification in Early Neural Development

- The vertebrate nervous system develops from ectoderm cells, which are initially arranged in a sheet formed during gastrulation. Folding of this ectodermal sheet (the neural plate) first forms the neural tube in the process of neurulation (see Figures 22-38 and 22-39).
- The notochord, a rod of mesoderm lying underneath (ventral to) the neural tube, is a source of signaling proteins that induce cell fates in surrounding tissues. For example, Sonic hedgehog (Shh) from the notochord influences the fates of nearby cells in the neural tube, somites, and endoderm.
- Shh is a morphogen that directs certain cell fates at high doses and other cell fates at lower doses. It tends to promote ventral fates, like floorplate. Its influence is tempered by other signals such as BMP, a TGFβ-type signal coming from overlying ectoderm that promotes dorsal neural fates (see Figure 22-40).
- The cells of the neural tube, which is initially one cell thick, proliferate and form neural precursor cells that migrate radially outward to form the layers of the brain and spinal cord.
- During normal *Drosophila* neurogenesis, only some ectodermal cells form neurons; others form other ectoderm-derived cells like skin. The balance between cell types is regulated by lateral inhibition involving Notch signaling. In this process, cells that have taken on a neural fate instruct surrounding cells not to do so (see Figures 22-41 and 22-42).

22.6 Growth and Patterning of Limbs

Vertebrate limb development provides a beautiful example of how the actions of individual cells combine to create pattern. Vertebrate limbs grow from small “buds” composed of an inner mass of mesoderm cells surrounded by a sheath of ectoderm (Figure 22-43). Hindlimbs and forelimbs are obviously related, as are left and right limbs. If the limbs were broken down into their constituent molecules or cells, the composition of all four would be nearly identical, yet their shapes differ in ways that are absolutely crucial to successful life. Pattern formation—that is, organizing those molecules and cells into a coherent whole—is a central goal of studying the molecular cell biology of limb development. Where would birds be with four legs instead of a pair each of legs and wings? Birds have in fact been a prime experimental animal for studies on limb development, since chick embryos can be readily accessed in the egg during the period of limb formation.

▲ **FIGURE 22-43 Limb development in the mouse.** Limb buds, which consist of an inner mass of mesoderm cells and outer layer of ectoderm, form at specific locations on the embryo’s flank. Outgrowth and patterning along the three axes leads to formation of the all the limb structures. [From L. Wolpert et al., 2001, *Principles of Development*, 2nd ed., Oxford University Press, Figure 10-5.]

In testing various theories of limb development in the chick, researchers have subjected embryos to transplantation, injected them with signaling proteins or signal-producing cells, and introduced retroviruses that direct gene expression in abnormal sites. The continued growth of the animal in the egg then is observed to see the effect of any particular treatment. Because it is relatively easy to reduce or eliminate a gene’s function in mice, genetic experiments have been useful in studying limb development in these animals. The results from the two experimental systems are largely in agreement.

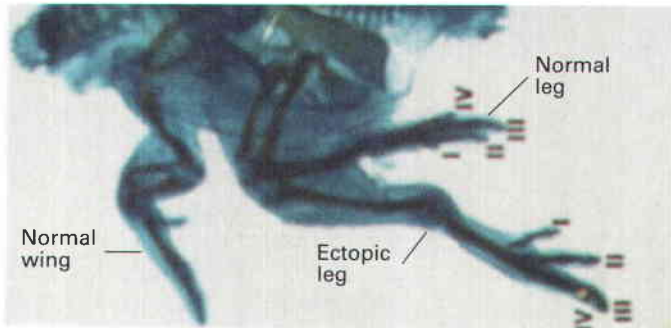

Hox Genes Determine the Right Places for Limbs to Grow

The first event in vertebrate limb development is determination of where, along the head-tail axis, limb growth will begin. We are not millipedes; decisions must be made. In both insects

(a) Effect of reduced or no FGF10

(b) Effect of ectopic FGF10

and vertebrates, the Hox genes control where limbs are made. The mesoderm that gives rise to limb buds, called *intermediate mesoderm*, is located adjacent to the somite mesoderm; mesoderm farther from somites is called *lateral plate mesoderm*. Expression of Hox genes in the intermediate mesoderm influences the position of limb-bud formation by controlling expression of genes (e.g., *Tbx* and *Pitx1*) that encode other transcription factors in the lateral plate mesoderm. The *Tbx* and *Pitx1* proteins, in turn, control production of secreted signals that are required for limb development.

Among these signals are fibroblast growth factor 10 (FGF10), which is secreted from cells in the lateral plate

◀ **EXPERIMENTAL FIGURE 22-44** The effect of altering FGF10 function on limb development in the mouse. (a) Gene knockout mice, lacking a functional part of the *fgf10* gene, were constructed by recombination. These photographs of mouse embryos a few days before birth show that mice heterozygous for the *fgf10* gene (+/-) are fairly normal, but homozygous mice (-/-) have severely impaired limb development compared with that in wild-type mice (+/+). These genetic data prove the importance of fibroblast growth factor 10 (FGF10), a secreted signal protein, for limb development. (b) To test whether FGF10 is capable of triggering limb development, experiments with chick embryos were done. These embryos are advantageous because the embryo can continue to grow after a surgical operation. Beads soaked in FGF10 protein were surgically implanted in the flank of a mid-stage chick embryo prior to limb development, in a region where no limb would normally develop. FGF10, but not control substances, was able to induce the formation of a fifth limb. The young chick shown here, from a FGF10-treated embryo, has an extra (ectopic) leg. Only half of the chick's skeleton is shown. [Part (a) from Min et al., 1998, *Genes & Devel.* **12**:3156. Part (b) from M. J. Cohn et al., 1995, *Cell* **80**:739.]

mesoderm and initiates outgrowth of a limb from specific regions of the embryo's flank. Mouse mutants lacking FGF10 develop without limbs (Figure 22-44a). Conversely, implantation of a bead soaked in FGF10 at sites in the flank of a chick embryo where a limb does not normally form causes an extra limb to grow (Figure 22-44b). These results demonstrate the remarkable inductive capabilities of FGF. Wnt signaling also plays a role in the initial outgrowth of limb buds.

Limb Development Depends on Integration of Multiple Extracellular Signal Gradients

The three axes of a limb bud and developed limb—anterior-posterior (thumb to little finger), dorsal-ventral (back of hand versus palm), and proximal-distal (shoulder to fingers)—are shown in Figure 22-45. Early limb development is marked by formation of two important signaling centers: the *apical ectodermal ridge (AER)*, a region of surface ectoderm at the distal tip of the emerging limb bud and the *zone of polarizing activity (ZPA)* in mesoderm at the posterior end of the bud.

▲ **FIGURE 22-45** The axes of the limb bud and the hand. A limb bud (left) and fully developed limb, a hand in this example (right), has three axes: anterior-posterior (thumb to little finger), proximal-distal (shoulder to fingers), and dorsal-ventral (back of

hand versus palm). In the developing limb bud, the apical ectodermal ridge (AER) is a source of fibroblast growth factor (FGF) signals, and the zone of polarizing activity (ZPA) is a source of Sonic hedgehog (Shh).

▲ FIGURE 22-46 Integration of three signals in vertebrate limb development along the proximal-distal and anterior-posterior axes. Each limb bud grows out of the flank of the embryo. (a) A fibroblast growth factor (FGF) signal, probably FGF10, comes from the mesoderm in specific regions of the embryo's flank, one region for each limb. FGF10 acts on a local region of surface ectoderm called the apical ectodermal ridge (AER) because it will form a prominent ridge. (b) The ectoderm that receives a FGF10 signal is induced to produce FGF8, another secreted signal. At the posterior end of the limb bud, FGF8 induces transcription of the *Sonic hedgehog* (*Shh*) gene. (c) Shh signaling induces transcription of the gene encoding FGF4 in the AER. FGF8 and FGF4 promote continued proliferation of the mesoderm cells, causing outgrowth of the limb bud. Shh also stimulates this outgrowth and confers posterior characteristics on the posterior part of the limb. Development along the dorsal-ventral axis depends on a Wnt signal that is not shown here.

In response to FGF10, the AER begins to secrete FGF8 and later FGF4. Both of these signals drive persistent division of mesoderm cells and therefore continued limb outgrowth. Sonic hedgehog (Shh) is produced in the ZPA of the posterior limb bud (Figure 22-46); indeed it is Shh secretion that defines the ZPA. The FGF signals confer a distal fate on cells in the limb bud, and Shh confers a posterior fate. If Shh is added to the anterior part of the bud, the limb that eventually forms will have two posterior patterns of bones in mirror-image, and no anterior. Along the dorsal-ventral axis, a Wnt7a signal directs cells to form ventral cell types. The Wnt7a, FGF4, and FGF8 signals promote the transcription of *Shh*, and Shh signaling promotes the transcription of the *Fgf4* and *Fgf8* genes. Thus the signals are mutually reinforcing in cells that are close enough; cells too far from one of the reinforcing signals will cease making their own signal. In this way, the strength and movement of signals is tied to the eventual size and shape of the limb.

The main developmental task in the formation of limbs and organs is to organize a few cell types (e.g., mesenchyme, vascular, epithelial) into complex multicellular structures. As we've just seen, cells in the midst of the limb bud are exposed to gradients of multiple signals (FGFs, Shh, and Wnt) that provide the initial guidelines for this building process. By integrating these signals, each cell is directed to express specific

transcription factors depending on its location relative to the three limb axes. The action of these transcription factors in turn control formation of the various parts of the limb.

Since each of the limb-bud signals must be produced in exactly the right cells, there is much interest in learning how their genes are controlled. The *Shh* gene, for example, is transcribed only in the ZPA cells of the posterior limb bud in response to FGF and other factors. Initial efforts to describe the transcriptional enhancer that controls *Shh* transcription in the limb bud failed. The mystery was solved when four families were found with a high frequency of polydactyly, an inherited abnormality marked by the presence of extra digits on the hands and feet. The mutation involved in each family mapped to a region of the genome in the vicinity of the human *Shh* gene, although the protein-coding parts of *Shh* were normal. These findings strongly suggested that damage to the enhancer controlling *Shh* transcription caused the abnormal development resulting in polydactyly in these families.

The *Shh* limb enhancer is quite remarkable in two respects. First, this regulatory sequence is located inside the transcription unit of another gene. Second, it is located about one million base pairs away from the *Shh* promoter! This is the Guinness record for long-distance regulation of gene transcription. Recent sequence comparisons have shown a high degree of sequence similarity throughout the ≈1-kb *Shh* enhancer in mice and humans. A smaller region of sequence similarity, the core sequence, also occurs in ricefish (Figure 22-47). All four polydactylous families were found to have mutations that changed the sequence of the *Shh* enhancer, as did two polydactylous mouse strains. These findings demonstrate the power of using the evolutionary conservation of DNA sequences to understand gene regulation and account for human disease.

Hox Genes Also Control Fine Patterning of Limb Structures

Once limb-bud growth and Shh production have gotten underway, Shh induces Hox-gene expression, starting at the posterior of the bud. Subsequently, expression of the Hox genes undergoes a complex series of changes and spreads more anteriorly along the bud. The transcription factors produced from *Hoxd11–Hoxd13* in posterior cells in turn stimulate expression of *Shh* in the posterior. As the bud grows during the period 9.0–10.5 days after fertilization, the domains of *Hoxd*-gene expression spread out (Figure 22-48). The Hox genes remain active in the distal limb bud, where digits will be formed. The combinations of Hox transcription factors in the cells of the developing limb bud, in their elaborate overlapping patterns, are responsible for fine-scale control of limb pattern. Humans carrying mutations in *Hoxd13* have an inherited limb malformation syndrome called *synpolydactyly*, marked by duplications of fingers and toes. This defect demonstrates the crucial nature of *Hoxd13* for normal limb development. In mice, deleting all *Hoxa* and *Hoxd* genes causes limbs to develop as short stubs without any distal structures, confirming the importance of Hox genes in mouse limb development.

▲ EXPERIMENTAL FIGURE 22-47 Mutations that cause polydactyly (extra digits) and evolutionary sequence conservation were used to identify the *Shh* enhancer. Members of four human families with a particular inherited form of polydactyly (extra digits) and two mouse strains with a similar defect were found to have mutations in a region located about 1 megabase (Mb) from the *Sonic hedgehog* (*Shh*) promoter. This region is located within a 31 kb intron of the *Lmbr1* gene (top). To find out if the mutations in this region are in fact responsible for polydactyly, scientists compared the nucleotide sequences of DNA from mice, humans, and rice fish. The top graph, plotting the percentage sequence identity between mouse and human DNA, indicates that the similarity is quite high in the

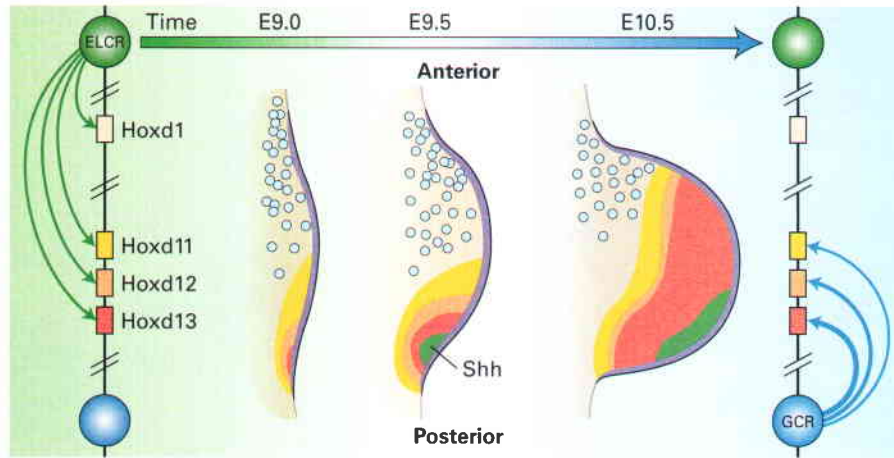

≈1-kb region containing the human mutations (black arrows) and mouse mutations (red arrows). Outside this region, the sequence similarity drops off dramatically. The bottom graph shows a far more limited region of similarity, referred to as the core, between mouse and rice fish DNA. These results suggested that the 1-kb region contains an enhancer controlling expression of *Shh* in the limb bud. In agreement with this idea, the mutant mice were found to express *Shh* in areas of the anterior limb bud where the gene should be off. Apparently, damage to the *Shh* limb-bud enhancer that changes spatial expression of *Shh* can result in defective limb patterning. [See L. A. Lettice et al., 2003, *Human Molec. Genet.* **12**:1725. Graphs adapted from T. M. Sagai et al., 2005, *Development* **132**:797.]

The *Shh* and the *Hoxd* genes regulate each other, forming a positive feedback loop in the posterior bud that keeps both genes turned on. In the anterior bud, a transcription factor called Gli3 represses the *Shh* and *Hoxd* genes. Shh signaling represses transcription of the *Gli3* gene in posterior cells (see Figure 22-48). The production of Hoxd transcription factors in distinct regions of the limb bud begs the question of which genes they control and how those target genes affect the pattern of the limbs. Little is known about either the identity or function of Hoxd target genes. Among the direct targets of Hoxd proteins is the gene encoding one of the ephrins, a family of membrane-bound signaling proteins (see Figure 23-42). Thus much work remains to be done to understand how the production of Hox transcription factors in

precise spatial patterns is translated into the exquisite and (within a species) highly reproducible shapes of limbs.

The final pattern in the limbs seems to be attained using repeated rounds of signaling and transcriptional control, with the early events roughing out the pattern and the later events refining it. At the same time that the limb is growing vigorously, the new cells are exposed to a mixture of pre-existing signals. Eventually apoptosis (Chapter 21) is triggered in specific cells, thus removing the webbing between the digits.

Our discussion of limb development has revealed an important feature of this and other developmental processes: the repeated use of the same kind of signals and regulators. Wnt signals initiate limb development and also control patterning along the dorsal-ventral axis of the limb bud.

▲ **FIGURE 22-48 Hox and Shh regulation in early limb buds.** E9, E9.5, E10.5 refer to embryonic days after fertilization. Transcription of the Hox genes in the limb bud is believed to be controlled by two enhancers: the general control region (GCR) and the early limb control region (ELCR). During limb development, the ELCR controls the initial patterns of Hox-gene expression as indicated, which includes *hoxd1*, and the GCR controls the later wave of Hox-gene transcription, which excludes *hoxd1*. The Hoxd11–Hoxd13 proteins

stimulate transcription of *Shh*. The diagram shows only *Hoxd* genes, but other Hox genes are expressed as well. The light blue circles represent Gli3 protein, a transcription factor that represses target genes that are controlled by Shh protein (e.g., the *Hoxd11–Hoxd13*) as well as the *Shh* gene itself. Shh protein turns off Gli3 transcription to activate its targets. [Adapted from J. Deschamps, 2004, *Science* 304:1610.]

Similarly, transcription factors encoded by Hox genes determine where limbs will form and then control digit patterning. And finally, FGF signals initiate limb-bud outgrowth (FGF10) and also maintain it (FGF4 and FGF8). The toolkit of developmentally important molecules is not too large, and the tools are used repeatedly to control cell fates.

So Far, So Good

In the preceding sections, we have witnessed many key events in the genesis of animal embryos:

- Construction of two quite different types of gametes and their fusion to restore a diploid genome with different patterns of gene expression by maternally and paternally derived chromosomes.
- Transformation of the fertilized egg (zygote) during cleavage and gastrulation into three layers of stem cells, the endoderm, mesoderm, and ectoderm, and the generation of a large number of inductive interactions between cells in different layers.
- Establishment of a dorsal-ventral axis, an anterior-posterior axis, and a left-right axis.
- Formation of the heart, the left-right asymmetric organ that will pump blood for a lifetime.
- Division of the early embryo into repeating body segments driven by different combinations of transcription factors distributed in space (insects) or cycles of gene expression that differ in time (vertebrates).
- Generation of distinctive features on each of the body-segment repeats, in both insects and vertebrates, as the result of Hox-gene activity.

- Folding of the ectoderm to create the neural tube and initial generation of the neurons that will make up the central nervous system.
- Selection of the sites where limbs will be located and their development along three axes.

But the embryo is not quite done. There is the matter of forming many other organs and tissues: skin, bone, muscle, eyes, vasculature, liver, kidney, gonads, lungs, gut and others . . . a lot of fascinating molecular cell biology. There is the sex-determination control system that makes half of us different from the other half, and the control of organ and body size. There is a need to wire the brain. There are regenerative processes and aging processes, all under the influence of genetic and environmental controls. We cannot discuss all these topics in this volume. But the principles of embryonic development described in this chapter are broadly applicable and allow scientists to use information about the development of one type of tissue or organ to guide studies of others.

KEY CONCEPTS OF SECTION 22.6

Growth and Patterning of Limbs

- The initiation of limb development at the right locations along the anterior-posterior body axis is initially controlled by Hox genes and other genes, leading to expression of signals that induce bud growth from specific regions of the embryo's flank.
- Limbs start as buds with an ectodermal sheath over a mesoderm filling (see Figure 22-45). Patterning within the limb bud involves cell-fate determination under the influence of three signaling systems that work simultaneously and influence the expression of each other in space- and time-dependent ways.

- Outgrowth of the limb bud along the proximal-distal axis is driven by a FGF signal that emerges from the apical ectodermal ridge (AER) at the outermost part of the bud. Patterning of the bud along the anterior-posterior axis depends upon Sonic hedgehog (Shh) signal produced in the zone of polarizing activity (ZPA) in the posterior bud (see Figure 22-46). A Wnt signal directs cells to form ventral cell types.
- Information from FGF, Shh, and Wnt signals is integrated by cells, so that each assumes its proper fate and role in the developing limb.
- Shh regulates expression of Hox genes in complex overlapping patterns during limb-bud development (see Figure 22-48). The Hox genes are important for regulating detailed pattern in the limb, for example, of the different digits and the bone, muscle, and nerve they contain.

Perspectives for the Future

You have undoubtedly noticed that the same classes of signals and transcription factors are used again and again during development of a polarized embryo. There are three reasons for this. First, much to the amazement and relief of biologists, the number of different classes of signals and of transcription factors is not too large, perhaps 20 different types of signals for example. For each type of signal, the standard signal-transduction pathway is quite well known (Chapter 16). Variations on the standard are interesting, but it is often fairly safe to predict what will happen when a particular signal (e.g., BMP) reaches a cell, and how to detect and measure the cell response to the signal. Second, the protein classes and gene systems involved in development are, to a high degree, conserved in most animals. This conservation has created a common “molecular genetic” language among biologists working on the development of many organisms, allowing them to share in discovery and understanding. Third, the patterns of evolution of development are becoming clear. Understanding how development is controlled allows us to understand much better how distinct animal forms can arise from mutations that change the actions of developmental regulators. What use is all this work, you might ask. Two answers seem obvious: understanding our origins and using our knowledge of animal development to prevent and treat human diseases.

Darwin understood the importance of embryology to his theory and wrote extensively on the subject. But the genetic and molecular cell biology mechanisms underlying evolution were completely unknown in his time. Now we have rich detail about how genes control animal form, and a flood of new information is pouring in. New fossils are found regularly of intermediate ancestral forms that link present-day animals. For example, fossils that appear to represent common ancestors to whales and hippos have been found, as well as the creature *Tiktaalik* that looks like a fish with scales, but has four legs. Such ancient creatures provide clues about how changes in developmental processes—pattern forming processes—underlie evolution. As the networks of interactions that control development of each particular tissue are traced, we will be able to

understand how alterations of some components can change animal form and function. Among all the changes that led to animal diversity—that made bats able to navigate by sonar and moths able to “sniff” single molecules and cheetahs that can run at 60 mph—were changes that made us what we are.

Genetic damage to any of the developmental regulators are likely to lead to birth defects, cancer, degenerative disease, and altered resistance to infection. Indeed, all of these conditions have been observed, and their relationship to faulty development established. Thus developmental biology is a rich source of new information about the causes of human disease. Since many proteins work in pathways, linking one developmental regulator to a disease has often led to identification of additional human genes tied to the same disease. Apart from *finding* human disease genes, there is the very real prospect of applying our knowledge of development to spur tissue regeneration and promote faster, better healing. Regeneration of blood cells from bone marrow transplants that contain hematopoietic stem cells is now a well-established procedure. There is every likelihood that a flood of new therapies will emerge as manipulation of signals and other developmental proteins becomes more precise and sophisticated. The ability to transfer knowledge from a wide variety of animal embryos to human biology, a triumph of evolutionary theory and practice, is a foundation for the next stages of medical advances.

Key Terms

acrosomal reaction 957	lateral inhibition 988
apical ectodermal ridge (AER) 991	maternal mRNAs 971
blastocyst 960	morphogen 964
cleavage 950	morphogenesis 969
cortical reaction 957	neurulation 985
dosage compensation system 958	notochord 987
epithelial-mesenchymal transitions 960	organogenesis 951
floral organ-identity genes 983	pair-rule genes 976
gametes 950	pattern formation 951
gap genes 972	segment-polarity genes 977
gastrulation 951	sensory organ precursor (SOP) 989
germ layers 951	somites 977
genomic imprinting 958	Spemann organizer 965
homeosis 979	syncytium 970
Hox genes 978	transcription cascade 974
induction 951	zone of polarizing activity (ZPA) 991

Review the Concepts

1. In differentiated cells, only selected genes are transcribed. Yet, except for lymphocytes and erythrocytes, most somatic cells contain the same nuclear genome. What evidence shows this is true?

2. Compare and contrast the action of morphogens involved in dorsal-ventral specification in *Xenopus laevis* and *Drosophila melanogaster*.

3. Using in situ hybridization with a probe specific for *dorsal* mRNA, where in the syncytial *Drosophila* embryo would you expect *dorsal* to be expressed? Using immunohistochemistry with an antibody specific for Dorsal protein, where would you expect to detect Dorsal protein?

4. A microarray analysis of wild-type fly embryos and *dorsal* mutant embryos would be expected to yield information on all genes regulated by Dorsal protein. Why? Other than new genes regulated by Dorsal, one would expect to see changes in regulation of previously identified genes. Expression of which genes would be increased or decreased in *dorsal* mutants?

5. Deleting the 3' UTR of the *bicoid* gene would yield what phenotype in a mutant fly? Why?

6. How can the group of five gap genes specify more than five types of cells in *Drosophila* embryos?

7. At which stage in embryological development do somites form? What factors affect their development?

8. What is homeosis? Give an example of a floral homeotic mutation and describe the phenotype of the mutant and the normal function of the wild-type gene product.

9. Hox-gene expression can be maintained through many cell generations. What molecular mechanisms are involved in this process?

10. Describe an experiment with *Xenopus* embryos that demonstrates the role of the Notch pathway in regulating the formation of neurons in vertebrates.

11. What is the evidence that a gradient of Sonic hedgehog leads to development of different cell types within the chick neural tube?

12. What evidence implicates fibroblast growth factor 10 (FGF10) in limb development?

13. Synpolydactyly is an inherited human abnormality characterized by duplicated fingers and toes. What type of mutation could cause this abnormality? What stage of development would be affected?

Analyze the Data

In *Drosophila*, maternally produced mRNAs and proteins that determine the body axes are transported from nurse cells into the developing oocyte. During early oogenesis, one of these maternal mRNAs, *oskar*, is dispersed throughout the oocyte and is not translated. By mid-oogenesis, *oskar* mRNA is transported to the posterior pole of the oocyte where it is translated; the Oskar protein then initiates formation of most abdominal segments and the germ-line cells. This developmental process is defective in *oskar* nonsense (*oskNS*) mutants. To further understand the role of *oskar* mRNA and its protein in *Drosophila* development, a new mutant (*oskX*) was generated (see A. Jenny et al., 2006, *Development* 133:2827-2833). In this fly mutant, the *oskar* gene contains a transposable element (TE) in its first exon (E1), as diagrammed here. For simplicity, introns are represented as thin black lines separating the exons:

a. Northern blot analysis using a probe complementary to *oskar* mRNA or to *rp49* mRNA was performed on mRNA isolated from egg chambers, which contain nurse cells and the developing oocyte, in wild-type and mutant flies. The results are shown in part (a) of the figure below. Micrographs of two egg chambers that were subjected to in situ hybridization with a probe directed against *oskar* mRNA are shown in part (b). The egg chamber on the left is from a wild-type female; the egg chamber on the right is from an *oskX* female. Hybridization appears as white staining in the micrographs.

What do these data suggest about the *oskX* mutation relative to the *oskNS* mutation? What is the purpose of probing for *rp49* mRNA?

b. Further study revealed that females hemizygous (only one allele present in the animal) for *oskNS* lay eggs that, when fertilized, develop into embryos lacking posterior structures. In contrast, females hemizygous for *oskX* produce oocytes that begin to form but then degenerate. What information do these observations provide about the function of Oskar protein?

c. The following rescue experiments were undertaken. Several transgenes carrying different domains of the *oskar* gene were constructed and introduced individually into females hemizygous for the *oskX* mutation. The ability of females expressing each transgene to lay eggs was then monitored. In all transgene constructs, the *oskar* promoter was replaced with a yeast inducible promoter (UAS). As diagrammed in part (a) of the

figure below, the first transgene construct includes the entire wild-type *oskar* gene with its three introns (UAS *osk*WT). For simplicity, introns are not depicted in the drawings. In the second construct, the wild-type *oskar* gene lacks its three introns (UAS *osk* Δ i(1,2,3)). In the third construct, 3' untranslated region (UTR) of the wild-type *oskar* gene is replaced with the 3' UTR from an irrelevant gene (UAS *osk*K10). The final construct contains only the 3' UTR of the *oskar* gene (UAS *osk*3'UTR). The relative egg-laying ability of the transgenic females is shown in part (b). The white bar (*w*¹¹¹⁸) is a measure of the eggs laid on average by nontransgenic wild-type females.

Offspring from females expressing transgenes 1 or 2 were normal, whereas those arising from females expressing transgene 4 lacked abdominal segments. What other information can be deduced from these observations about the role of *oskar* in *Drosophila* development?

USING LETHAL MUTATIONS TO STUDY DEVELOPMENT

C. Nüsslein-Volhard and E. Wieschaus, 1980, *Nature* 287:795

One of the most fascinating questions in developmental biology concerns the proper formation of an embryo. How does a fertilized egg “know” how to form a complex organism? Scientists have puzzled over how to address this question for a long time. In 1980, Christiane Nüsslein-Volhard and Eric Wieschaus first reported studies with the fruit fly *Drosophila melanogaster* in which a genetic approach was used to address this question.

Background

To examine complex processes such as development of an embryo from a fertilized egg, biologists often collect mutant organisms that differ from the normal (wild-type) organism. To apply this genetic approach to developmental biology, geneticists first look for mutant organisms that display an obvious defect in overall formation. Early work uncovered a number of genes involved in the development of the fruit fly *Drosophila melanogaster*. In the first genes examined, the mutations resulted in the birth of flies with obvious physical defects, such as the presence of an extra set of wings. Because this approach relied on examining viable flies with physical malformations, it missed many developmentally important genes that, when mutated, result in the death of the fly embryo.

In the late 1970s, Nüsslein-Volhard and Wieschaus began their pioneering work on the development of *Drosophila* embryos. They sought to identify as many genes in the developmental process as possible by looking for genes that, when mutated, resulted in the death of the embryonic fly. Their work unveiled several key genes active in the early development of not only *Drosophila*, but higher organisms as well.

The Experiment

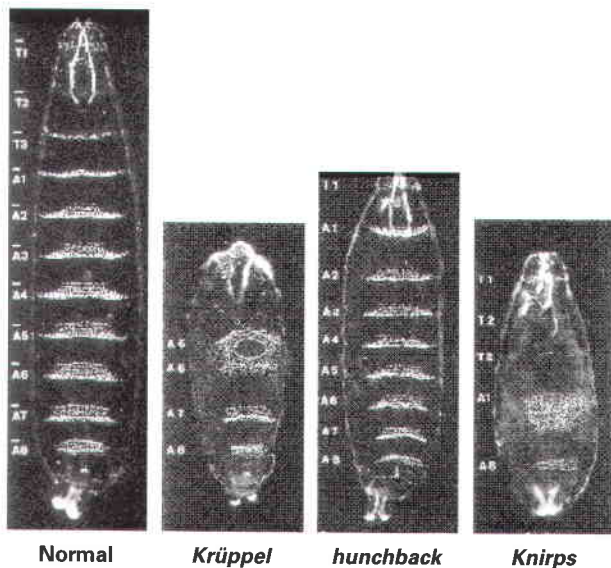

Geneticists develop systematic methods, known as genetic screens, to search for mutations that affect biological processes. Nüsslein-Volhard and Wieschaus had to consider several previous observations on *Drosophila* development when they designed their screen. First, they knew that genes expressed in the egg, called *maternal-effect genes*, as well as genes expressed after fertilization in the developing embryo, called *zygotically active genes*, controlled the early development of an embryo. They chose to focus on isolating mutations that affect the zygotically active genes. Second, they had to consider that the *Drosophila* genome is diploid, which means that the progeny receive a copy of each gene from both parents. Scientists had previously demonstrated that *Drosophila* required only a single wild-type copy of most genes in order to develop into a viable fly. This made it likely that recessive mutations in developmentally active genes would *not* result in embryonic death, the phenotypic screen used by Nüsslein-Volhard and Wieschaus. Therefore, they had to breed mutant *Drosophila* to obtain flies that were homozygous for the mutations of interest.

The overall mutation rate in a naturally occurring population is quite low. If a geneticist were to search for mutants in a natural population, he or she would have to examine a large number of individuals. To circumvent this difficulty, Nüsslein-Volhard and Wieschaus induced mutations in a *Drosophila* population at the onset of the screen by feeding a mutagenic chemical to male flies and mating them to a genetically defined population of wild-type female flies in a process known as a genetic cross. The resulting

progeny would be heterozygous for any mutations on the chromosomes they received from the father. The heterozygotes were then bred as separate lines, in essence isolating each new mutation in a separate fly stock. Flies within each stock then were crossed with each other to generate homozygous embryos. If the mutation affected a gene needed for embryogenesis, the homozygous embryos would die but could be examined for phenotype. The mutant gene, however, would not be lost as it could be recovered in the heterozygous flies of that same stock.

Using this screen, Nüsslein-Volhard and Wieschaus amassed a large collection of mutant flies. The next step was to assign the various mutants to specific classes, based on their phenotype. They focused on the segmentation of the larvae. Whereas all mutants in their screen necessarily displayed the phenotype of embryonic lethality, they differed greatly in their segmentation defects. To classify these defects, Nüsslein-Volhard and Wieschaus examined the larvae under the microscope. They compared the body pattern of a wild-type viable larva to those of the embryonic lethal mutants. By comparing these patterns, they uncovered three classes of genes that affect segmentation, which they called *gap*, *pair-rule*, and *segment-polarity*.

Gap mutants are missing up to eight segments from the overall body, which results in a smaller body due to the death of some of the embryo cells. Three mutants—*knirps*, *hunchback*, and the previously characterized *Krüppel*—fell into this class, as shown in the accompanying photographs. The next class of mutants, the pair-rule mutants, had deletions of alternating segments of the body, which caused roughly half-normal-size larval bodies to form. Six

◀ **FIGURE 1** A viable, wild-type larva (Normal) is compared with three larvae that have mutations in the gap genes *Krüppel*, *hunchback*, or *knirps*. Thoracic segments are labeled T1–T3, whereas abdominal segments are designated A1–A8. Gap mutants are missing entire segments from the body plan, as illustrated by the labeled segments on the left. [From C. Nüsslein-Volhard and E. Wieschaus, 1980, *Nature* **287**:795.]

previously uncharacterized mutants—*paired*, *even-skipped*, *odd-skipped*, *odd-paired*, *fushi tarazu*, and *runt*—were placed in this class. The final set of mutants, the segment-polarity mutants, had the same overall number of segments as wild-type larvae. But a part of the body pattern within each segment was deleted in each mutant. The deleted portion of the pattern within each segment was replaced by a mirror image of the portion that remained. Nüsslein-Volhard and Wieschaus’s initial screen uncovered six mutants of this class, three of which—*gooseberry*, *hedgehog*, and *patched*—had not been previously observed.

Discussion

In the first published report of their screen, Nüsslein-Volhard and Wieschaus described 15 mutations that affected segmentation. Of these, only five were

in previously identified genes. When they completed the study—often referred to as the Heidelberg screens—they had identified 139 different genes that, when mutated, resulted in embryonic death. These mutants fell into 17 different classes including the ones described here. Together these genes act in a field of equivalent cells and direct each cell to take on a fate appropriate to its position within the field. In this way some cells form segment anterior, some make bristles, some make sensory organs, and so forth. Genes that control these sorts of organizing cell-fate decisions are called *pattern-formation genes*. As molecular techniques evolved, scientists cloned many of these genes and characterized their gene products. These mutants formed the base for the next quarter century of research into the development of *Drosophila*. Moreover, many vertebrate pattern-formation genes are close homologs of the corresponding

fly genes, and use similar molecular mechanisms to organize cells, tissues, and organs. Thus the work of Nüsslein-Volhard and Wieschaus greatly advanced the study of development in all vertebrates, including ourselves.

The majority of genes identified by Nüsslein-Volhard and Wieschaus encode transcription factors, but their screen also uncovered genes encoding signaling molecules, receptors, enzymes, adhesion molecules, cytoskeleton proteins, and some proteins whose functions remain unknown. Mammalian genes related to some of the *Drosophila* genes uncovered by Nüsslein-Volhard and Wieschaus subsequently were found to be important in human diseases such as cancer and birth defects. In 1995, the Nobel Foundation awarded its prize for Physiology and Medicine to Nüsslein-Volhard and Wieschaus for their pioneering work.

NERVE CELLS

When humans wish to view themselves as the pinnacle of evolution, the assertion is usually related to the brain, since many of our other abilities fare poorly in comparison with other animals. The complexity of the human brain is staggering and seems adequate to account for its amazing abilities. In the 1.3-kg adult human brain (78 percent of which is water!), there are about 10^{11} nerve cells, called neurons. The number of human brain neurons is comparable to the estimated 10^{11} stars in our galaxy, the Milky Way. The neurons in one human brain are connected by some 10^{14} synapses, the junction points where two or more neurons communicate. With 6.5×10^9 people on the earth, there are about 6.5×10^{23} human synapses in existence, which is also about the total number of stars in the universe . . . so far as we know. Using our neurons, we can keep searching for more.

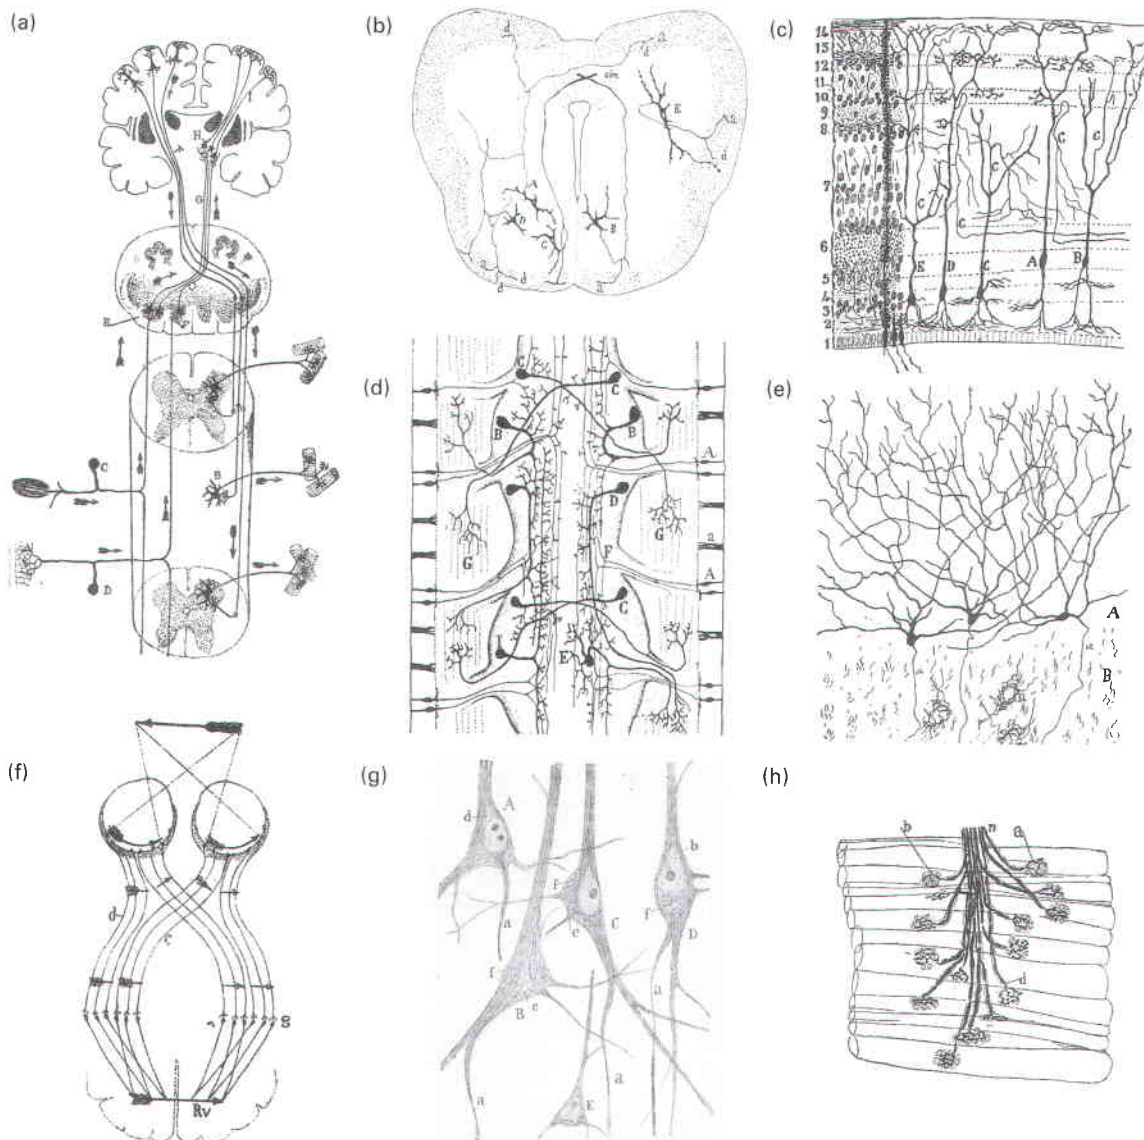

Right this moment you are vigorously employing neurons to detect and interpret visual information. Neurons gobble ATP, made exclusively from glucose, at a tremendous rate. Although the brain is only about 2 percent of the body's mass, it uses about 20 percent of the body's resting energy. This extensive brain energy is used to drive electrical signaling along neurons, which are often elongated cells, and chemical signaling between them. The electrical pulses that travel along neurons are called action potentials, and information is encoded as the frequency at which action potentials are fired. Owing to the speed of electrical transmission, neurons are champion signal transducers, much faster than cells that secrete hormones or developmental signaling proteins. The rapidity of neural signaling makes it possible to handle large amounts of information quickly. The amazing

complexity of our neural network makes possible sophisticated perception, analysis, and response, and forms the cellular machinery underlying instinct, learning, memory, and emotion.

In this chapter we will focus on neurobiology at the cell and molecular level. We will start by looking at the general architecture of neurons and at how they carry signals (Figure 23-1). Next, we will look at ion flow, channel proteins, and membrane properties: how electrical pulses move rapidly along neurons. Third, we will examine communication between neurons: electrical signals traveling along a cell must be translated into a chemical pulse between cells and then back into an electrical signal in the receiving cells. In the

fourth section we will examine neurons in sensory tissues: how visual, touch, auditory, taste, and olfactory information is collected, processed, and interpreted. Finally we will explore the systems that guide nerves as they grow: how signaling systems initially organize the “wiring diagram.”

The speed, precision, and integrative power of neural signaling makes possible accurate and timely sensory perception of a swiftly changing environment, and is the basis of high-throughput signal processing and analysis. We refer to the processing as “thinking,” and molecular cell biology is at the heart of it.

23.1 Neurons and Glia: Building Blocks of the Nervous System

In this section we take an initial look at the structure of neurons and how they propagate electrical and chemical signals. Neurons are distinguished by their elongated, asymmetric shape, by their highly localized proteins and organelles, and most of all by a set of proteins that controls the flow of ions across the plasma membrane. Because one neuron can respond to the inputs from multiple neurons, generate electrical

signals, and transmit the signals to multiple neurons, a nervous system has considerable powers of signal analysis. For example, a neuron might pass on a signal only if it receives five simultaneous activating signals from input neurons. The receiving neuron measures both the total *amount* of incoming signal and whether the five signals are roughly *synchronous*. Input from one neuron to another can be either excitatory—combining with other signals to trigger electrical transduction in the receiving cell—or inhibitory, discouraging such transmission. Thus the properties and connections of individual neurons set the stage for integration and refinement of information. We will begin by looking at how signals are received and sent, and in subsequent parts of the chapter we will look at the molecular details of the machinery involved.

Information Flows Through Neurons from Dendrites to Axons

Neurons arise from roughly spherical *neuroblast* precursors. Newly born neurons can migrate long distances while still in the form of simple round cells before growing into dramatically elongated cells. Fully differentiated neurons take many forms, but generally share certain key features (see Figure 23-1). The nucleus is found in a rounded part of the cell called the *cell body* (Figure 23-2). Branching cell processes called **dendrites** (from the Greek for “treelike”) are found at one end, and are the main structure where signals are received from other neurons via synapses. Incoming signals are also received at synapses that form on neuronal cell bodies. Neurons often have extremely long dendrites with complex branches, particularly in the central nervous system. This allows them to form synapses with, and receive signals from, a large number of other neurons—up to tens of thousands. Thus the converging dendritic branches allow signals from many cells to be received and integrated by a single neuron.

When a neuron is first differentiating, the end of the cell opposite the dendrites undergoes dramatic outgrowth to form a long extended arm called the **axon**, which is essentially a transmission wire. The growth of axons must be controlled so that proper connections are formed, a process called axon guidance that is discussed in Section 23.5. The diameters of axons vary from just a micrometer in certain nerves of the human brain to a millimeter in the giant fiber of the squid. Axons can be meters in length (in giraffe necks, for example), and are often partly covered with electrical insulation called the **myelin sheath** (see Figure 23-2b), which is made up of cells called **glia**. The insulation speeds electrical transmission and prevents short circuits. The short, branched ends of the axon at the opposite end of the neuron from the dendrites are called the *axon termini*. This is where signals are passed along to the next neuron. The asymmetry of the neuron, with dendrites at one end and axon termini at the other, is indicative of the unidirectional flow of information from dendrites to axons.

For all the impressiveness of neurons, they are a minority population of cells in the human brain. Glia, cells that play many roles in the brain but do not themselves conduct electrical impulses, outnumber neurons by about 10 to 1 in humans. One of their roles is to produce myelin sheaths, but they have other important roles. Much current work is devoted to learning how glia build the myelin insulators that control neuronal electrical transmission, provide growth factors and other signals to neurons, receive signals from neurons, and influence the formation of synapses.

Information Moves as Pulses of Ion Flow Called Action Potentials

Nerve cells are members of a class of *excitable cells*, which also includes muscle cells, cells in the pancreas, and some others. The term indicates that the cells can build up a voltage across their plasma membranes, the **membrane potential** and

(a) Multipolar interneuron

(b) Motor neuron

◀ **FIGURE 23-2 Typical morphology of two types of mammalian neurons.** Action potentials arise in the axon hillock and are conducted toward the axon terminus. (a) A multipolar interneuron has profusely branched dendrites, which *receive* signals at synapses with several hundred other neurons. Small voltage changes imparted by inputs in the dendrites can sum to give rise to the more massive action potential, which starts in the hillock. A single long axon that branches laterally at its terminus *transmits* signals to other neurons. (b) A motor neuron innervating a muscle cell typically has a single long axon extending from the cell body to the effector cell. In mammalian motor neurons, an insulating sheath of myelin usually covers all parts of the axon except at the nodes of Ranvier and the axon terminals. The myelin sheath is composed of cells called *glia*.

that this voltage can be discharged (allowed to come back to zero voltage or even swing to positive) in various ways and for various purposes (Chapter 11). The voltage in a typical neuron, called the *resting potential* because it is the state when no signal is in transit, is established by ion pumps in the plasma membrane. The pumps use energy, in the form of ATP, to move positively charged ions out of the cell. The result is a net negative charge inside the cell compared with the outside environment. A typical resting potential is -60 mV.

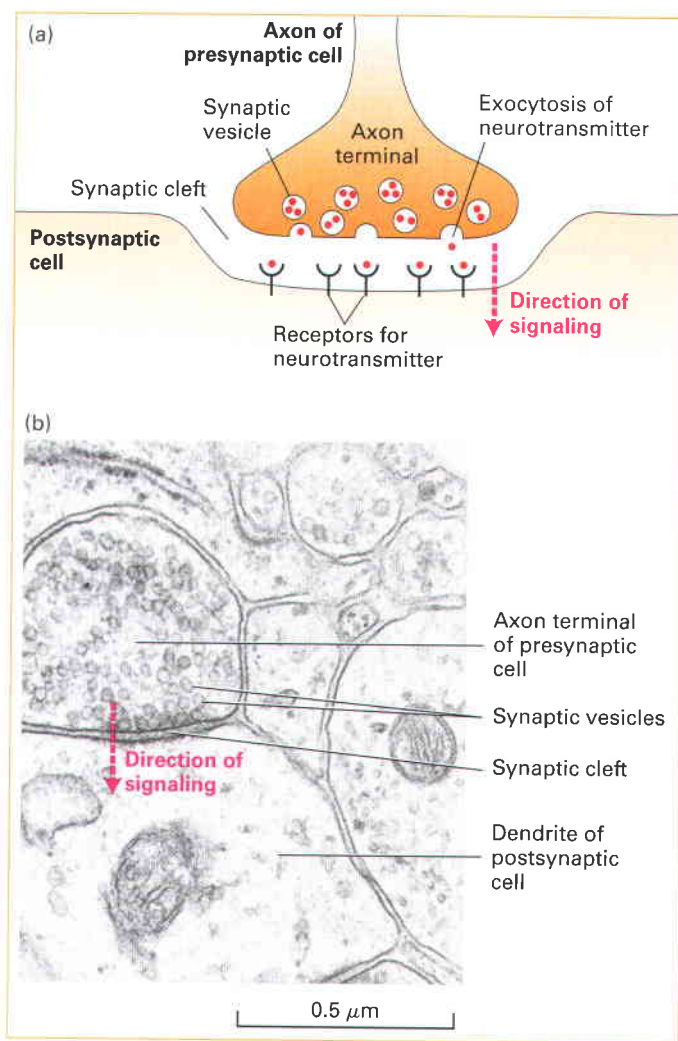

Neurons have a language all their own. The signals take the form of brief local voltage changes, from negative inside to positive, an event designated **depolarization**. A powerful surge of depolarizing voltage change, moving from one end of the neuron to the other, is called an **action potential**. “Depolarization” is somewhat of a misnomer, since the neuron goes from negative inside to neutral to positive inside, which could be accurately described as depolarization followed by the opposite polarization (Figure 23-3). At the peak of an action potential, the membrane potential can be as much as $+50$ mV (inside positive), a net change of ≈ 110 mV. As we shall see in greater detail in Section 23.2, the voltage change (which is eventually added to other voltage changes to create the action potential) begins at the dendrite end of the cell in response to inputs from other cells and moves along the axon to the axon terminus. Action potentials move at speeds up to 100 meters per second. In humans, for instance, axons may be more than a meter long, yet it takes only a few milliseconds for an action potential to move along their length. Neurons can fire repeatedly after a brief recovery period, for example, every 4 ms, as in Figure 23-3. After the action potential passes a sector of a neuron, channel proteins and pumps restore the negative-inside resting potential (*repolarization*). The restoration process chases the action potential down the axon to the terminus, leaving the neuron ready to signal again. Action po-

▲ **EXPERIMENTAL FIGURE 23-3** Recording of an axonal membrane potential over time reveals the amplitude and frequency of action potentials. An action potential is a sudden, transient depolarization of the membrane, followed by repolarization to the resting potential of about -60 mV. The axonal membrane potential can be measured with a small electrode placed into it (see Figure 11-18). This recording of the axonal membrane potential in this neuron shows that it is generating one action potential about every 4 milliseconds.

tentials are all or none. Once the threshold to start one is reached, a full firing occurs. The signal information is therefore carried primarily not by the intensity of the action potentials, but by the timing and frequency of them.

Some excitable cells are not neurons. Muscle contraction is triggered by motor neurons that synapse directly with excitable muscle cells (see Figure 23-2b). Insulin secretion from the beta cells of the pancreas is triggered by neurons. In both cases the activating event involves an opening of plasma

▲ **FIGURE 23-4** A chemical synapse. (a) A narrow region—the synaptic cleft—separates the plasma membranes of the presynaptic and postsynaptic cells. Arrival of action potentials at a synapse causes release of neurotransmitters (red circles) by the presynaptic cell, their diffusion across the synaptic cleft, and their binding by specific receptors on the plasma membrane of the postsynaptic cell. Generally these signals depolarize the postsynaptic membrane (making the potential inside less negative), tending to induce an action potential in it. (b) Electron micrograph shows a dendrite synapsing with an axon terminal filled with synaptic vesicles. In the synaptic region, the plasma membrane of the presynaptic cell is specialized for vesicle exocytosis; synaptic vesicles containing a neurotransmitter are clustered in these regions. The opposing membrane of the postsynaptic cell (in this case, a neuron) contains receptors for the neurotransmitter. [Part (b) from C. Raine et al., eds., 1981, *Basic Neurochemistry*, 3d ed., Little, Brown, p. 32.]

membrane channels that causes changes in the transmembrane flow of ions and in the electrical properties of the regulated cells.

Information Flows Between Neurons via Synapses

What starts an action potential? Axon termini from one neuron are closely apposed to dendrites of another, at the junction called a **synapse** (Figure 23-4). The axon termini of the *presynaptic cell* use exocytosis to release small molecules called **neurotransmitters**. Neurotransmitters, glutamate or acetylcholine, for example, diffuse across the synapse in about 0.5 ms and bind to receptors on the dendrite of the adjacent neuron. Binding of neurotransmitter triggers opening or closing of specific ion channels in the plasma membrane of *postsynaptic cell* dendrites, leading to changes in the membrane potential at this point. The ensuing local depolarization, if large enough, triggers an action potential. Transmission is unidirectional, from the axon termini of the presynaptic cell to dendrites of the postsynaptic cell. In some synapses, the effect of the neurotransmitters is to hyperpolarize and therefore lower the likelihood of an action potential in the postsynaptic cell. A single axon in the central nervous system can synapse with many neurons and induce responses in all of them simultaneously. Conversely, sometimes multiple neurons must act on the postsynaptic cell roughly synchronously to have a strong enough impact to trigger an action potential. Neuronal integration of depolarizing and hyperpolarizing signals determines the likelihood of an action potential.

Thus neurons employ a combination of extremely fast electrical transmission *along* the axon with rapid chemical

communication *between* cells. Now we will look at how a chain of neurons, a circuit, can achieve a useful function.

The Nervous System Uses Signaling Circuits Composed of Multiple Neurons

In complex multicellular animals, such as insects and mammals, various types of neurons form signaling circuits. A *sensory neuron* reports an event that has happened, like the arrival of a flash of light or the movement of a muscle. A *motor neuron* carries a signal to a muscle to stimulate its contraction (Figure 23-5, and see Figure 23-2b). An *interneuron* bridges other neurons, sometimes allowing integration or divergence of signals, sometimes extending the reach of a signal. In a simple type of circuit called a *reflex arc* interneurons connect multiple sensory and motor neurons, allowing one sensory neuron to affect multiple motor neurons and one motor neuron to be affected by multiple sensory neurons; in this way interneurons integrate and enhance reflexes. For example, the knee-jerk reflex in humans (see Figure 23-5) involves a complex reflex arc in which one muscle is stimulated to contract while another is inhibited from contracting. The reflex also sends information to the brain to announce what happened. Such circuits allow an organism to respond to a sensory input by the coordinated action of sets of muscles that together achieve a single purpose.

These simple signaling circuits, however, do not directly explain higher-order brain functions such as reasoning, computation, and memory development. Typical neurons in the brain receive signals from up to a thousand other neurons and, in turn, can direct chemical signals to many other neurons. The output of the nervous system depends on its circuit

▲ **FIGURE 23-5 The knee-jerk reflex.** A tap of the hammer stretches the quadriceps muscle, thus triggering electrical activity in the stretch receptor sensory neuron. The action potential, traveling in the direction of the top blue arrow, sends signals to the brain so we are aware of what is happening, and also to two kinds of cells in the dorsal-root ganglion that is located in the spinal cord. One cell, a motor neuron that connects back to the quadriceps (red), stimulates muscle

contraction so that you kick the person who hammered your knee. The second connection activates, or “excites,” an inhibitory interneuron (black). The interneuron has a damping effect, blocking activity by a flexor motor neuron (green) that would, in other circumstances, activate the hamstring muscle that opposes the quadriceps. In this way, relaxation of the hamstring is coupled to contraction of the quadriceps. This is a reflex because movement requires no conscious decision.

properties—the wiring, or interconnections, between neurons and the strength of these interconnections. Complex aspects of the nervous system, such as vision and consciousness, cannot be understood at the single-cell level, but only at the level of networks of nerve cells that can be studied by techniques of systems analysis. The nervous system is constantly changing; alterations in the number and nature of the interconnections between individual neurons occur, for example, in the formation of new memories.

KEY CONCEPTS OF SECTION 23.1

Neurons and Glia: Building Blocks of the Nervous System

- Neurons are highly asymmetric cells composed of dendrites at one end, a cell body containing the nucleus, a long axon, and axon termini.
- Neurons carry information from one end to the other using pulses of ion flow across the plasma membrane. Branched cell processes, dendrites, at one end of the cell receive chemical signals from other neurons, triggering ion flow. The electrical signal moves rapidly to axon termini at the other end of the cell (see Figure 23-2).
- Glial cells are ten times as abundant as neurons and serve many purposes such as building the insulation that coats neurons and supporting the formation of new synapses.
- A resting neuron carrying no signal has protein pumps that move ions across the plasma membrane. The movement of ions such as K^+ and Na^+ and Cl^- creates a net negative charge inside the cell. This voltage is called the resting potential and usually is about -60 mV (see Figure 23-3).
- If a stimulus causes channel proteins to open so that ions can flow more freely, a strong pulse of voltage change may pass down the neuron from dendrites to axon termini. The cell goes from being -60 mV inside to $+50$ mV inside, relative to the extracellular world. This pulse is called an action potential.
- The action potential travels down the neuron because a change in voltage near the dendrites triggers a change in voltage in the cell body, which in turn does the same to the proximal and then distal axon, and so forth.
- Neurons connect across small gaps called synapses. Since an action potential cannot jump the gap, at the axon termini of the presynaptic cell the signal is converted from electrical to chemical to stimulate the postsynaptic cell.
- Upon stimulation by an action potential, axon termini release, by exocytosis, small packets of chemicals called neurotransmitters. Neurotransmitters diffuse across the synapse and bind to receptors on the dendrites on the other side of the synapse. These receptors initiate a new action potential in the postsynaptic cell (see Figure 23-4).
- Neurons form circuits. They may consist of sensory neurons, interneurons, and motor neurons, as in the knee-jerk response (see Figure 23-5).

23.2 Voltage-Gated Ion Channels and the Propagation of Action Potentials in Nerve Cells

Action potentials are propagated because a change in voltage in one part of the cell triggers the opening of channels in the next section of the cell. *Voltage-gated channels* therefore lie at the heart of neural transmission (Chapter 11). In this section, we first introduce some of the key properties of action potentials, which move rapidly along the axon. We then describe how the voltage-gated channels responsible for propagating action potentials in neurons operate. Thus electric signals carry information within a nerve cell, while chemical signals, discussed in the next section, carry information from one neuron to another, or from a neuron to a muscle or other target cell.

The Magnitude of the Action Potential Is Close to E_{Na}

Operation of the Na^+/K^+ pump generates a high concentration of K^+ and a low concentration of Na^+ in the cytosol, relative to those in the extracellular medium (Chapter 11). The subsequent outward movement of K^+ ions through nongated K^+ channels is driven by the K^+ concentration gradient (cytosol $>$ medium), generating the resting membrane potential. The entry of Na^+ ions into the cytosol from the medium also is thermodynamically favored, driven by the Na^+ concentration gradient (medium $>$ cytosol) and the inside-negative membrane potential (see Figure 11-24). However, most Na^+ channels in the plasma membrane are closed in resting cells, so little inward movement of Na^+ ions can occur (Figure 23-6a).

If enough Na^+ channels open, the resulting influx of Na^+ ions will more than compensate for the efflux of K^+ ions through open resting K^+ channels. The result would be a *net* inward movement of cations, generating an excess of positive charges on the cytosolic face and a corresponding excess of negative charges (owing to the Cl^- ions “left behind” in the extracellular medium after influx of Na^+ ions) on the extracellular face (Figure 23-6b). In other words, the plasma membrane is depolarized to such an extent that the inside face becomes positive.

The magnitude of the membrane potential at the peak of depolarization in an action potential is very close to the Na^+ equilibrium potential E_{Na} given by the Nernst equation (Equation 11-2), as would be expected if opening of voltage-gated Na^+ channels is responsible for generating action potentials. For example, the measured peak value of the action potential for the squid giant axon is 35 mV, which is close to the calculated value of E_{Na} (55 mV) based on Na^+ concentrations of 440 mM outside and 50 mM inside. The relationship between the magnitude of the action potential and the concentration of Na^+ ions inside and outside the cell has been confirmed experimentally. For instance, if the concentration of Na^+ ions in the solution bathing the squid axon is reduced to one-third of normal, the magnitude of the depolarization is reduced by 40 mV, nearly as predicted.

▲ FIGURE 23-6 Depolarization of the plasma membrane due to opening of gated Na^+ channels. (a) In resting neurons, a type of nongated K^+ channel is partially open, but the more numerous gated Na^+ channels are closed. The movement of K^+ ions outward establishes the inside-negative membrane potential characteristic of most cells. (b) Opening of gated Na^+ channels permits an influx of sufficient Na^+ ions to cause a reversal of the membrane potential. In the depolarized state, voltage-gated K^+ channels open and subsequently repolarize the membrane. Note that the flows of ions are too small to have much effect on the overall concentration of either Na^+ or K^+ in the cytosol or exterior fluid.

Sequential Opening and Closing of Voltage-Gated Na^+ and K^+ Channels Generate Action Potentials

The cycle of changes in membrane potential and return to the resting value that constitutes an action potential lasts 1–2 milliseconds and can occur hundreds of times a second in a typical neuron (see Figure 23-3). These cyclical changes in the membrane potential result from the sequential opening and closing first of *voltage-gated Na^+ channels* and then of *voltage-gated K^+ channels*. The role of these channels in the generation of action potentials was elucidated in classic studies done on the giant axon of the squid, in which multiple microelectrodes can be inserted without causing damage to the integrity of the plasma membrane. However, the same basic mechanism is used by all neurons.

Voltage-Gated Na^+ Channels As just discussed, voltage-gated Na^+ channels are closed in resting neurons. A small depolarization of the membrane causes a conformational change in these channel proteins that opens a gate on the cytosolic surface of the pore, permitting Na^+ ions to pass through the pore into the cell. The greater the initial membrane depolarization, the more voltage-gated Na^+ channels that open and the more Na^+ ions that enter.

As Na^+ ions flow inward through opened channels, the excess positive charges on the cytosolic face and negative

charges on the exoplasmic face diffuse a short distance away from the initial site of depolarization. This *passive spread* of positive and negative charges depolarizes (makes the inside less negative) adjacent segments of the plasma membrane, causing opening of additional voltage-gated Na^+ channels in these segments and an increase in Na^+ influx. As more Na^+ ions enter the cell, the inside of the cell membrane becomes more depolarized, causing the opening of yet more voltage-gated Na^+ channels and even more membrane depolarization, setting into motion an explosive entry of Na^+ ions. For a fraction of a millisecond, the permeability of this region of the membrane to Na^+ becomes vastly greater than that for K^+ , and the membrane potential approaches E_{Na} , the equilibrium potential for a membrane permeable only to Na^+ ions. As the membrane potential approaches E_{Na} , however, further net inward movement of Na^+ ions ceases, since the concentration gradient of Na^+ ions (outside > inside) is now offset by the inside-positive membrane potential E_{Na} . The action potential is, at its peak, close to the value of E_{Na} .

Figure 23-7 schematically depicts the critical structural features of voltage-gated Na^+ channels and the conformational changes that cause their opening and closing. In the resting state, a segment of the protein on the cytosolic face—the *gate*—obstructs the central pore, preventing passage of ions. A small depolarization of the membrane triggers movement of positively charged *voltage-sensing* α helices toward the exoplasmic surface, causing a conformational change in the gate that opens the channel and allows ion flow. After about 1 ms, further Na^+ influx is prevented by movement of the cytosol-facing *channel-inactivating segment* into the open channel. As long as the membrane remains depolarized, the channel-inactivating segment remains in the channel opening; during this *refractory period*, the channel is inactivated and cannot be reopened. A few milliseconds after the inside-negative resting potential is reestablished, the channel-inactivating segment swings away from the pore and the channel returns to the closed resting state, once again able to be opened by depolarization.

Voltage-Gated K^+ Channels The repolarization of the membrane that occurs during the refractory period is due largely to opening of voltage-gated K^+ channels. The subsequent increased efflux of K^+ from the cytosol removes the excess positive charges from the cytosolic face of the plasma membrane (i.e., makes it more negative), thereby restoring the inside-negative resting potential. Actually, for a brief instant the membrane becomes hyperpolarized. At the peak of this **hyperpolarization**, the potential approaches E_{K} , which is more negative than the resting potential (see Figure 23-3).

Opening of the voltage-gated K^+ channels is induced by the large depolarization of the action potential. Unlike voltage-gated Na^+ channels, most types of voltage-gated K^+ channels remain open as long as the membrane is depolarized, and close only when the membrane potential has returned to an inside-negative value. Because the voltage-gated K^+ channels open slightly after the initial depolarization, at the height of the action potential, they sometimes are called *delayed K^+ channels*. Eventually all the voltage-gated K^+ and Na^+ channels return to their closed resting state. The only

▲ FIGURE 23-7 Operational model of the voltage-gated Na^+ channel. Four transmembrane domains in the protein contribute to the central pore through which ions move. The critical components that control movement of Na^+ ions are shown here in the cutaway views depicting three of the four transmembrane domains. **1** In the closed, resting state, the voltage-sensing α helices, which have positively charged side chains every third residue, are attracted to the negative charges on the cytosolic side of the resting membrane. This keeps the gate segment in a position that blocks the channel, preventing entry of Na^+ ions. **2** In response to a small depolarization, the voltage-sensing helices rotate in a screwlike

manner toward the outer membrane surface, causing an immediate conformational change in the gate segment that opens the channel. **3** The voltage-sensing helices rapidly return to the resting position, and the channel-inactivating segment moves into the open channel, preventing passage of further ions. **4** Once the membrane is repolarized, the channel-inactivating segment is displaced from the channel opening and the gate closes; the protein reverts to the closed, resting state and can be opened again by depolarization. [See W. A. Catterall, 2001, *Nature* **409**:988; M. Zhou et al., 2001, *Nature* **411**:657; and B. A. Yi and L. Y. Jan, 2000, *Neuron* **27**:423.]

open channels in this baseline condition are the non-gated K^+ channels that generate the resting membrane potential, which soon returns to its usual value (see Figure 23-6a).

The patch-clamp tracings in Figure 23-8 reveal the essential properties of voltage-gated K^+ channels. In this experiment, small segments of a neuronal plasma membrane were

held clamped at different voltages, and the flux of electric charges through the patch due to flow of K^+ ions through open K^+ channels was measured. At the modest depolarizing voltage of -10 mV , the channels in the membrane patch open infrequently and remain open for only a few milliseconds, as judged, respectively, by the number and width of

▲ EXPERIMENTAL FIGURE 23-8 Probability of channel opening and current flux through individual voltage-gated K^+ channels increases with the extent of membrane depolarization. These patch-clamp tracings were obtained from patches of neuronal plasma membrane clamped at three different potentials, $+50$, $+20$, and -10 mV . The upward deviations in the current indicate the opening of K^+ channels and movement of

K^+ ions outward (cytosolic to exoplasmic face) across the membrane. Increasing the membrane depolarization (i.e., the clamping voltage) from -10 mV to $+50\text{ mV}$ increases the probability a channel will open, the time it stays open, and the amount of electric current (numbers of ions) that pass through it. [From B. Pallota et al., 1981, *Nature* **293**:471, as modified by B. Hille, 1992, *Ion Channels of Excitable Membranes*, 2d ed., Sinauer, p. 122.]

the upward blips on the tracings. Further, the ion flux through them is rather small, as measured by the electric current passing through each open channel (the height of the blips). Depolarizing the membrane further to +20 mV causes these channels to open about twice as frequently. Also, more K⁺ ions move through each open channel (the height of the blips is greater) because the force driving cytosolic K⁺ ions outward is greater at a membrane potential of +20 mV than at -10 mV. Depolarizing the membrane further to +50 mV, the value at the peak of an action potential, causes opening of more K⁺ channels and also increases the flux of K⁺ through them. Thus, by opening during the peak of the action potential, these K⁺ channels permit the outward movement of K⁺ ions and repolarization of the membrane potential while the voltage-gated Na⁺ channels are closed and inactivated.

More than 100 voltage-gated K⁺ channel proteins have been identified in humans and other vertebrates. As we discuss later, all these channel proteins have a similar overall structure, but they exhibit different voltage dependencies, conductivities, channel kinetics, and other functional properties. Many open only at strongly depolarizing voltages, a property required for generation of the maximal depolarization characteristic of the action potential before repolarization of the membrane begins.

Action Potentials Are Propagated Unidirectionally Without Diminution

The generation of an action potential relates to the changes that occur in a small patch of the neuronal plasma membrane. At the peak of the action potential, passive spread of the membrane depolarization is sufficient to depolarize a neighboring segment of membrane. This causes a few voltage-gated Na⁺ channels in this region to open, thereby increasing the extent of depolarization in this region and causing an explosive opening of more Na⁺ channels and generation of an action potential. This depolarization soon triggers opening of voltage-gated K⁺ channels and restoration of the resting potential. The action potential thus spreads as a traveling wave away from its initial site without diminution.

As noted earlier, during the refractory period voltage-gated Na⁺ channels are inactivated for several milliseconds. Such previously opened channels cannot open during this period even if the membrane is depolarized owing to passive spread. As illustrated in Figure 23-9, the inability of Na⁺ channels to reopen during the refractory period ensures that action potentials are propagated only in one direction, from the axon initial segment where they originate to the axon terminus. This property of the Na⁺ channels also limits the number of action potentials per second that a neuron can conduct. This is important, since it is the frequency of action potentials that carries the information. Reopening of Na⁺ channels upstream of an action potential (i.e., closer to the cell body) also is delayed by the membrane hyperpolarization that results from opening of voltage-gated K⁺ channels.

Nerve Cells Can Conduct Many Action Potentials in the Absence of ATP

The depolarization of the membrane during an action potential results from movement of just a small number of Na⁺ ions into a neuron and does not significantly affect the intracellular Na⁺ concentration. A typical nerve cell has about 10 voltage-gated Na⁺ channels per square micrometer (μm^2) of plasma membrane. Since each channel passes ≈ 5000 – $10,000$ ions during the millisecond it is open (see Figure 11-22), a maximum of 10^5 ions per μm^2 of plasma membrane will move inward during each action potential.

To assess the effect of this ion flux on the cytosolic Na⁺ concentration of 10 mM (0.01 mol/L), typical of a resting axon, we focus on a segment of axon 1 micrometer (μm) long and 10 μm in diameter. The volume of this segment is $78 \mu\text{m}^3$, or 7.8×10^{-14} liters, and it contains 4.7×10^8 Na⁺ ions: (10^{-2} mol/L) (7.8×10^{-14} L) (6×10^{23} Na⁺/mol). The surface area of this segment of the axon is $31 \mu\text{m}^2$, and during passage of one action potential, 10^5 Na⁺ ions will enter per μm^2 of membrane. Thus this Na⁺ influx increases the number of Na⁺ ions in this segment by only one part in about 150: $(4.7 \times 10^8) \div (3.1 \times 10^6)$. Likewise, the repolarization of the membrane due to the efflux of K⁺ ions through voltage-gated K⁺ channels does not significantly change the intracellular K⁺ concentration.

Because so few Na⁺ and K⁺ ions move across the plasma membrane during each action potential, the ATP-driven Na⁺/K⁺ pump that maintains the usual ion gradients plays no direct role in impulse conduction. Since the ion movements during each action potential involve only a minute fraction of the cell's K⁺ and Na⁺ ions, a nerve cell can fire hundreds or even thousands of times in the absence of ATP.

All Voltage-Gated Ion Channels Have Similar Structures

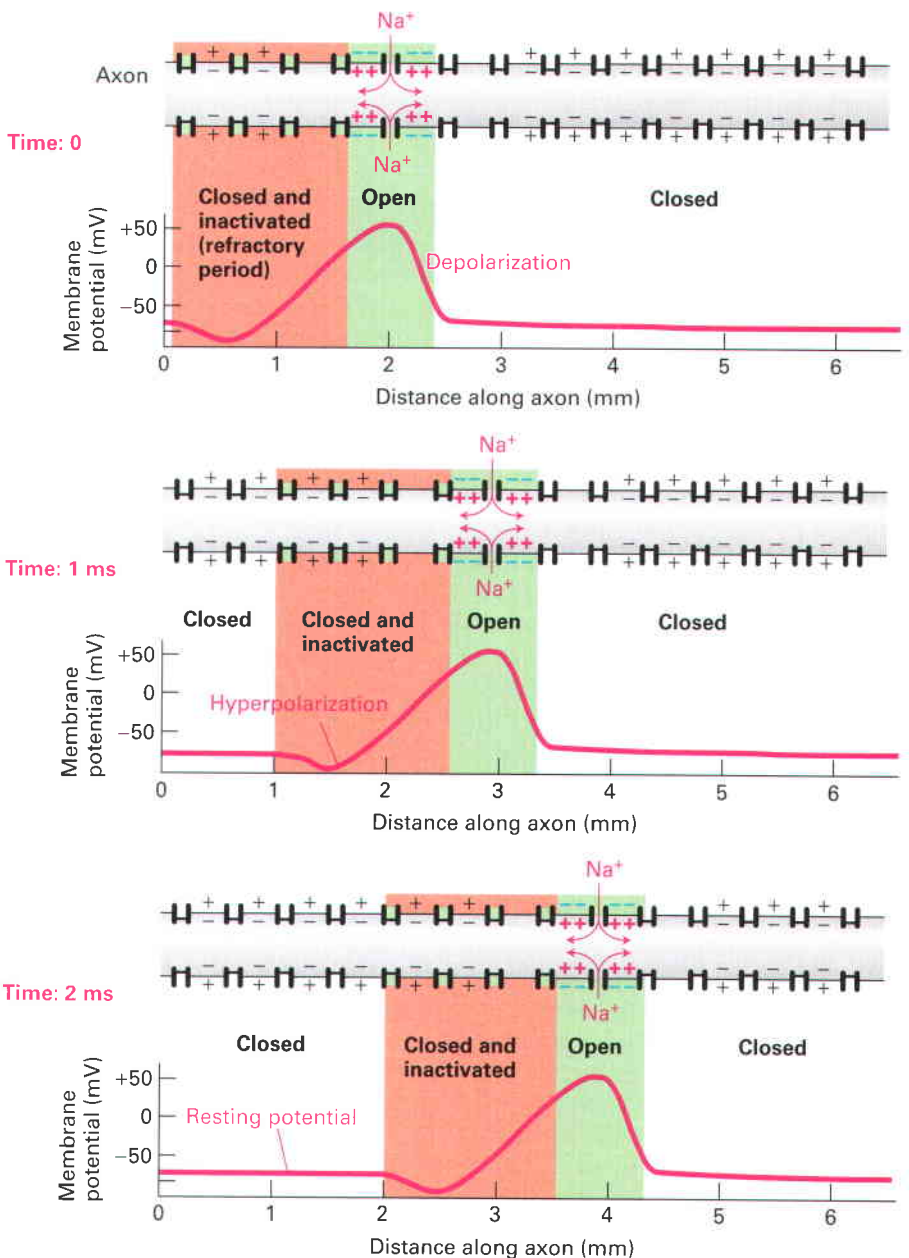

Having explained how the action potential is dependent on regulated opening and closing of voltage-gated channels, we turn to a molecular dissection of these remarkable proteins. After describing the basic structure of these channels, we focus on three questions:

- How do these proteins sense changes in membrane potential?
- How is this change transduced into opening of the channel?
- What causes these channels to become inactivated shortly after opening?

The initial breakthrough in understanding voltage-gated ion channels came from analysis of fruit flies (*Drosophila melanogaster*) carrying the *shaker* mutation. These flies shake vigorously under ether anesthesia, reflecting a loss of motor control and a defect in certain motor neurons that have an abnormally prolonged action potential. Researchers suspected that the *shaker* mutation caused a defect in channel function. Cloning of the gene involved confirmed that

► **FIGURE 23-9 Unidirectional conduction of an action potential due to transient inactivation of voltage-gated Na⁺ channels.**

At time 0, an action potential (red) is at the 2-mm position on the axon; the Na⁺ channels at this position are open and Na⁺ ions are flowing inward. The excess Na⁺ ions diffuse in both directions along the inside of the membrane, passively spreading the depolarization. Because the Na⁺ channels at the 1-mm position are still inactivated (green), they cannot yet be reopened by the small depolarization caused by passive spread; the Na⁺ channels at the 3-mm position, in contrast, begin to open. Each region of the membrane is refractory (inactive) for a few milliseconds after an action potential has passed. Thus, the depolarization at the 2-mm site at time 0 triggers action potentials downstream only; at 1 ms an action potential is passing the 3-mm position, and at 2 ms an action potential is passing the 4-mm position.

the defective protein was a channel. The *shaker* mutation prevents the mutant channel from opening normally immediately upon depolarization. To test whether the wild-type *shaker* gene encoded a K⁺ channel, cloned wild-type *shaker* cDNA was used as a template to produce *shaker* mRNA in a cell-free system. Expression of this mRNA in frog oocytes and patch-clamp measurements on the newly synthesized channel protein showed that its functional properties were identical with those of the voltage-gated K⁺ channel in the neuronal membrane, demonstrating conclusively that the *shaker* gene encodes this K⁺-channel protein.

The Shaker K⁺ channel and most other voltage-gated K⁺ channels that have been identified are tetrameric proteins composed of four identical subunits arranged in the membrane around a central pore. Each subunit is constructed of six membrane-spanning α helices, designated S1–S6, and a P

segment (Figure 23-10a). The S5 and S6 helices and the P segment are structurally and functionally homologous to those in the nongated resting K⁺ channel discussed earlier (see Figure 11-19). The S5 and S6 helices form the lining of the channel through which the ion travels. The S1–S4 helices act as a voltage sensor (with S4 acting as the primary sensor) and are described as paddles owing to the way they protrude from the central complex. The N-terminal “ball” extending into the cytosol from S1 is the channel-inactivating segment.

Voltage-gated Na⁺ channels and Ca²⁺ channels are monomeric proteins organized into four homologous domains, I–IV (Figure 23-10b). Each of these domains is similar to a subunit of a voltage-gated K⁺ channel. However, in contrast to voltage-gated K⁺ channels, which have four channel-inactivating segments, the monomeric voltage-gated channels have a single channel-inactivating segment. Except for this

◀ **FIGURE 23-10** Schematic depictions of the secondary structures of voltage-gated K^+ and Na^+ channels. (a) Voltage-gated K^+ channels are composed of four identical subunits, each containing 600–700 amino acids, and six membrane-spanning α helices, S1–S6. The N-terminus of each subunit, located in the cytosol and labeled N, forms a globular domain (orange ball) essential for inactivation of the open channel. The S5 and S6 helices (green) and the P segment (blue) are homologous to those in nongated resting K^+ channels, but each subunit contains four additional transmembrane α helices. One of these, S4 (red), is the primary voltage-sensing α helix and is assisted in this role by helices S1–3. (b) Voltage-gated Na^+ channels are monomers containing 1800–2000 amino acids organized into four transmembrane domains (I–IV) that are similar to the subunits in voltage-gated K^+ channels. The single channel-inactivating segment, located in the cytosol between domains III and IV, contains a conserved hydrophobic motif (H; yellow). Voltage-gated Ca^{2+} channels have a similar overall structure. Most voltage-gated ion channels also contain regulatory (β) subunits that are not depicted here. [Part (a) adapted from C. Miller, 1992, *Curr. Biol.* 2:573, and H. Larsson et al., 1996, *Neuron* 16:387; part (b) adapted from W. A. Catterall, 2001, *Nature* 409:988.]

minor structural difference and their varying ion permeabilities, all voltage-gated ion channels are thought to function in a similar manner and to have evolved from a monomeric ancestral channel protein that contained six transmembrane α helices.

Voltage-Sensing S4 α Helices Move in Response to Membrane Depolarization

The understanding of channel-protein biochemistry is advancing rapidly owing to new crystal structures for bacterial and *shaker* potassium channels and other channels. One method used to obtain crystals of these difficult membrane proteins was to surround them with bound fragments of monoclonal antibodies (Fab's; Chapter 24); in other cases they were crystallized in complexes with normal protein-binding partners.

The structures of the channels reveal remarkable arrangements of the voltage-sensing domains, and suggest how parts of the protein move in order to open the channel. The tetramer has a pore whose walls are formed by helices S5 and S6 (Figure 23-11a). Outside that core structure four arms, or “paddles,” protrude into the surrounding membrane; these are the voltage sensors, and they are in minimal contact with the pore. Sensitive electric measurements suggested that the opening of a voltage-gated Na^+ or K^+ channel is accompanied by the movement of 12–14 protein-bound positive charges from the cytosolic to the exoplasmic surface of the membrane. The moving part of the protein is composed of helices S1–S4; S4 accounts for much of the positive charge and is therefore the primary voltage sensor, with a positively charged lysine or arginine every third or fourth residue. Arginines in S4 have been measured moving as much as 1.5

nm as the channel opens, which can be compared with the ≈ 5 -nm thickness of the membrane or the 1.2-nm diameter of the α helix itself. The movement of these gating charges (or voltage sensors) under the force of the electric field triggers a conformational change in the protein that opens the channel. Thus the S4 helix is the key part of the voltage sensor, which then moves the S1–S4 helices across much of the membrane. The most unusual aspect of the voltage-sensitive channel structures is the presence of charged groups, e.g., arginines, in contact with lipid. The location of the voltage sensor helps to explain earlier experiments where a non-voltage-sensitive channel was converted into a voltage-sensing channel by adding to it voltage-sensing domains. Such an experiment would seem unlikely to work if the voltage sensors had to be deeply embedded in the core structure.

Studies with mutant *Shaker* K^+ channels support the importance of the S4 helix in voltage sensing. When one or more arginine or lysine residues in the S4 helix of the *Shaker* K^+ channel were replaced with neutral or acidic residues, fewer positive charges than normal moved across the membrane in response to a membrane depolarization, indicating that arginine and lysine residues in the S4 helix do indeed move across the membrane. In other studies, mutant *Shaker* proteins in which various S4 residues were converted to cysteine were tested for their reactivity with a water-soluble cysteine-modifying chemical agent that cannot cross the membrane. On the basis of whether the cysteines reacted with the agent added to one side or the other of the membrane, the results indicated that in the resting state amino acids near the C-terminus of the S4 helix face the cytosol; after the membrane is depolarized, some of these same amino

▲ FIGURE 23-11 Molecular structure of a voltage-sensitive potassium channel. The two ribbon diagrams show models of the potassium channel in (a) open and (b) closed states. Since the molecule is a tetramer of the same subunit, four copies of each helix are visible; the ones farthest away are seen only dimly. The brown (S5) and green (S6) alpha helices span the membrane, with the interior of the cell at the bottom and exterior at the top. The purple spheres represent K^+ ions, which pass through the open channel and occupy part of the closed channel without passing through. The S6 (green) helices line the pore. Note how the helices are tightly packed at the bottom in (b), closing the channel so that the K^+ ion cannot pass through. [compare the distances between S5 helices as shown by the arrows below (a) and (b).] The S4–S5 linker, located in the cytoplasm, connects the S4 helix (not shown) to the S5 helix (brown). For clarity, helices S1 through S4 have been omitted from the model; they would normally be attached to the end of the S4–S5 linker and protrude from the molecule as the voltage-sensing “paddles.” These paddles move from

near the interior to the exterior of the membrane in response to depolarization. Since each one is attached to an S4–S5 linker, each linker and its attached S5 helix is moved, in turn moving S6 helices, which opens the pore. The structure of the open mammalian channel (a) has been determined. The closed-channel structure in (b) is hypothetical, but is based on observations of a closed bacterial potassium-channel structure. (c) The ball-and-chain model for inactivation of voltage-gated K^+ channels in three-dimensional cutaway view of the inactive state. In addition to the four α subunits (tan and gray) that form the channel, these channel proteins have four regulatory β subunits (purple). At the N terminus of each of the β subunit proteins is a small domain (purple “ball”) on the end of the purple “chain” that controls the opening of the central pore. In this illustration the N terminus of one subunit has moved through a lateral window to block the pore. [Parts (a) and (b) from S. B. Long, E. B. Campbell, and R. MacKinnon, 2005, *Science* **309**:903–908; part (c) adapted from R. Aldrich, 2001, *Nature* **411**:643, and M. Zhou et al., 2001, *Nature* **411**:657.]

acids become exposed to the exoplasmic surface of the channel. These experiments directly demonstrated movement of the S4 helix across the membrane, as schematically depicted in Figure 23-7 for voltage-gated Na^+ channels.

The structure of the open form of a mammalian Shaker K^+ channel has been contrasted with the closed structure of a crystallized bacterial K^+ channel. The results suggest a model for the closing of the channel in response to movements of the voltage sensors across the membrane (Figure 23-11a, b). In the model, the voltage sensors, composed of helices S1–S4, move in response to voltage and exert a

torque on a linker helix that connects S4 to S5. In the open-channel conformation, the position of the S4–S5 linkers allows the S5 helices to lie at about a 45° angle to the plane of the membrane (Figure 23-11a, brown helices), and the pore inside has a 1.2-nm opening. When the cell is repolarized and the voltage sensor moves toward the intracellular membrane surface, the S4–S5 linkers are twisted down, toward the inside of the cell. The S5 helices are consequently moved more orthogonal to the plane of the membrane (Figure 23-11b, brown helices). This position leaves the S5 and S6 helices in closer proximity, squeezing the channel closed (Figure 23-11a, b; the

double headed arrows indicate spacing between adjacent S5 helices). Thus the gate probably is composed of the cytosol-facing ends of the S5 and S6 helices, where the pore is narrowest.

Movement of the Channel-Inactivating Segment into the Open Pore Blocks Ion Flow

An important characteristic of most voltage-gated channels is inactivation; that is, soon after opening they close spontaneously, forming an inactive channel that will not reopen until the membrane is repolarized. In the resting state, the positively charged globular balls at the N-termini of the four subunits in a voltage-gated K^+ channel are free in the cytosol. Several milliseconds after the channel is opened by depolarization, one ball moves through an opening (*lateral window*) between two of the subunits and binds in a hydrophobic pocket in the pore's central cavity, blocking the flow of K^+ ions (Figure 23-11c). After a few milliseconds, the ball is displaced from the pore, and the protein reverts to the closed, resting state. The ball-and-chain domains in K^+ channels are functionally equivalent to the channel-inactivating segment in Na^+ channels.

The experimental results shown in Figure 23-12 demonstrate that inactivation of K^+ channels depends on the ball domains, occurs after channel opening, and does not require the ball domains to be covalently linked to the channel protein. In other experiments, mutant K^+ channels lacking portions of the ≈ 40 -residue chain connecting the ball to the S1

▲ **EXPERIMENTAL FIGURE 23-12 Experiments with a mutant K^+ channel lacking the N-terminal globular domains support the ball-and-chain inactivation model.** The wild-type Shaker K^+ channel and a mutant form lacking the amino acids composing the N-terminal ball were expressed in *Xenopus* oocytes. The activity of the channels then was monitored by the patch-clamp technique. When patches were depolarized from -0 to $+30$ mV, the wild-type channel opened for ≈ 5 ms and then closed (red curve). The mutant channel opened normally, but could not close (green curve). When a chemically synthesized ball peptide was added to the cytosolic face of the patch, the mutant channel opened normally and then closed (blue curve). This demonstrated that the added peptide inactivated the channel after it opened and that the ball does not have to be tethered to the protein in order to function. [From W. N. Zagotta et al., 1990, *Science* **250**:568.]

helix were expressed in frog oocytes. Patch-clamp measurements of channel activity showed that the shorter the chain, the more rapid the inactivation, as if a ball attached to a shorter chain can move into the open channel more readily. Conversely, addition of random amino acids to lengthen the normal chain slows channel inactivation.

The single channel-inactivating segment in voltage-gated Na^+ channels contains a conserved hydrophobic motif composed of isoleucine, phenylalanine, methionine, and threonine (see Figure 23-10b). Like the longer ball-and-chain domain in K^+ channels, this segment folds into and blocks the Na^+ -conducting pore until the membrane is repolarized (see Figure 23-7).

Myelination Increases the Velocity of Impulse Conduction

As we have seen, action potentials can move down an axon without diminution at speeds up to 1 meter per second. But even such fast speeds are insufficient to permit the complex movements typical of animals. In humans, for instance, the cell bodies of motor neurons innervating leg muscles are located in the spinal cord, and the axons are about a meter in length. The coordinated muscle contractions required for walking, running, and similar movements would be impossible if it took 1 second for an action potential to move from the spinal cord down the axon of a motor neuron to a leg muscle. The solution is to wrap cells in insulation that increases the rate of movement of an action potential. The insulation is called a **myelin sheath** (see Figure 23-2b). The presence of a myelin sheath around an axon increases the velocity of impulse conduction to 10–100 meters per second. As a result, in a typical human motor neuron, an action potential can travel the length of a 1-meter-long axon and stimulate a muscle to contract within 0.01 seconds.

In nonmyelinated neurons, the conduction velocity of an action potential is roughly proportional to the diameter of the axon, because a thicker axon will have a greater number of ions that can diffuse. The human brain is packed with relatively small, myelinated neurons. If the neurons in the human brain were not myelinated, their axonal diameters would have to increase about 10,000-fold to achieve the same conduction velocities as myelinated neurons. Thus vertebrate brains, with their densely packed neurons, never could have evolved without myelin.

Action Potentials “Jump” from Node to Node in Myelinated Axons

The myelin sheath surrounding an axon is formed from many glial cells. Each region of myelin formed by an individual glial cell is separated from the next region by an unmyelinated area of axonal membrane about $1 \mu\text{m}$ in length called the *node of Ranvier* (or simply, *node*; see Figure 23-2). The axonal membrane is in direct contact with the extracellular

▲ FIGURE 23-13 Conduction of action potentials in myelinated axons. Because voltage-gated Na^+ channels are localized to the axonal membrane at the nodes of Ranvier, the influx of Na^+ ions associated with an action potential can occur only at nodes. When an action potential is generated at one node (step **1**), the excess positive ions in the cytosol, which cannot move outward across the sheath, diffuse rapidly down the axon, causing sufficient depolarization at the next node (step **2**) to induce an action potential at that node (step **3**). By this mechanism the action potential jumps from node to node along the axon.

fluid only at the nodes. Moreover, all the voltage-gated Na^+ channels and all the Na^+/K^+ pumps, which maintain the ionic gradients in the axon, are located in the nodes.

As a consequence of this localization, the inward movement of Na^+ ions that generates the action potential can occur only at the myelin-free nodes (Figure 23-13). The excess cytosolic positive ions generated at a node during the membrane depolarization associated with an action potential spread passively through the axonal cytosol to the next node with very little loss or attenuation, since they cannot cross the myelinated axonal membrane. This causes a depolarization at one node to spread rapidly to the next node, permitting the action potential, in effect, to jump from node to node. The transmission is called *saltatory conduction*. This phenomenon explains why the conduction velocity of myelinated neurons is about the same as that of much larger diameter unmyelinated neurons. For instance, a 12- μm -diameter myelinated vertebrate axon and a 600- μm -diameter unmyelinated squid axon both conduct impulses at 12 m/s.

Glia Produce Myelin Sheaths and Synapses

Of the four types of glia (three of which are shown in Figure 23-14), two produce myelin sheaths: *oligodendrocytes* make sheaths for the central nervous system (CNS), and *Schwann cells* make them for the peripheral nervous system. *Astrocytes*, a third type, are necessary for neurons to produce synapses and use them to communicate with other neurons. The fourth type, *microglia*, produce survival fac-

tors for cells and carry out immune functions. These cells participate in inflammatory responses and constitute a part of the CNS immune system. They can differentiate to form phagocytic cells with characteristics of macrophages (Chapter 24). Microglia form in the bone marrow, are not related by lineage to neurons or to other glia, and will not be discussed further.

Oligodendrocytes Oligodendrocytes form the spiral myelin sheath around axons of the central nervous system (Figure 23-14c). Each oligodendrocyte provides myelin sheaths to multiple neurons. The major protein constituents are myelin basic protein (MBP) and proteolipid protein (PLP). MBP, a peripheral membrane protein found in both the CNS and the PNS, has seven RNA splicing variants that encode different forms of the protein. It is synthesized by ribosomes located in the growing myelin sheath (Figure 23-14c), an example of specific transport of mRNAs to a peripheral cell region. The localization of MBP mRNA depends on microtubules.

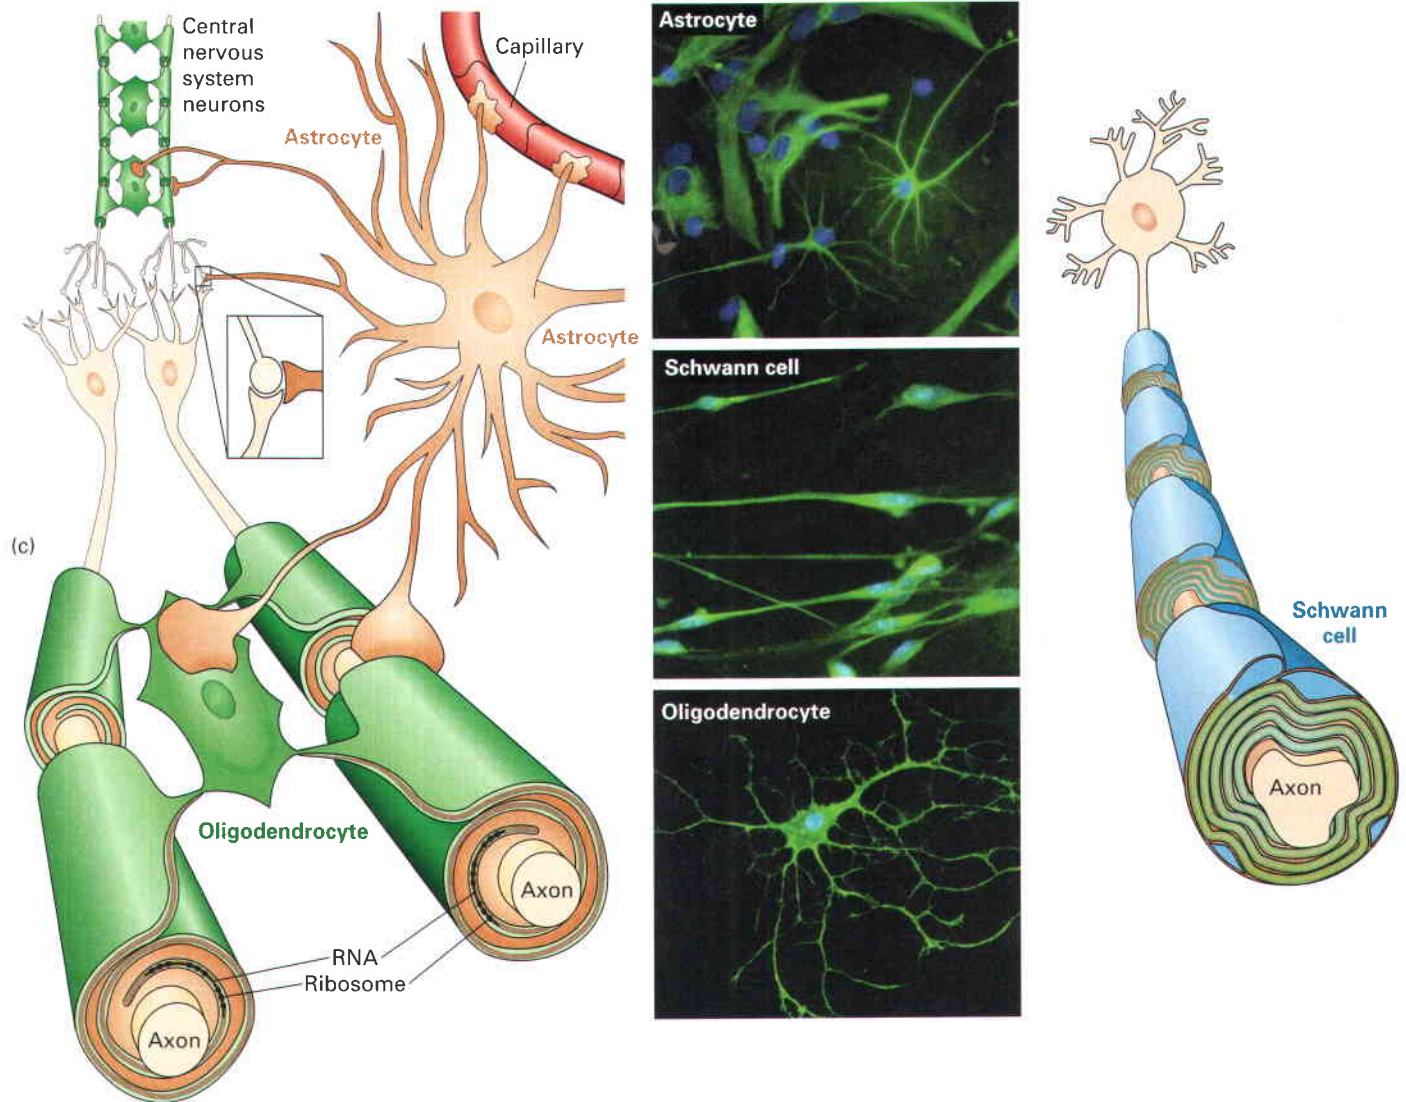

☠ Damage to proteins produced by oligodendrocytes underlies a prevalent human neurological disease, multiple sclerosis (MS). MS is usually characterized by spasms and weakness in one or more limbs, bladder dysfunction, local sensory losses, and visual disturbances. This disorder—the prototype *demyelinating disease*—is caused by patchy loss of myelin in areas of the brain and spinal cord. In MS patients, conduction of action potentials by the demyelinated neurons is slowed, and the Na^+ channels spread outward from the nodes, lowering their nodal concentration. The cause of the disease is not known but appears to involve either the body's production of auto-antibodies (antibodies that bind to normal body proteins) that react with MBP or the secretion of proteases that destroy myelin proteins. A mouse mutant, *shiverer*, has a deletion of much of the MBP gene, leading to tremors, convulsions, and early death. Similarly human (Pelizaeus-Merzbacher disease) and mouse (*jimpy*) mutations in the gene coding for the other major protein of CNS myelin, PLP, cause loss of oligodendrocytes and inadequate myelination. ■

Schwann Cells Schwann cells form myelin sheaths around peripheral nerves. A Schwann cell myelin sheath is a remarkable spiral wrap (see Figure 23-14b). A long axon can have as many as several hundred Schwann cells along its length, each contributing insulation to an *internode* stretch of about 1–1.5 μm of axon. Not all axons are myelinated, for reasons that are not known. Mutations in mice that eliminate Schwann cells cause the death of most neurons.

In contrast to oligodendrocytes, Schwann cells each dedicate themselves to one axon. The sheaths are composed of about 70 percent lipid (rich in cholesterol) and 30 percent protein. In the peripheral nervous system the principle protein constituent (~80 percent) of myelin is called protein 0 (P_0), an integral membrane protein that has immunoglobulin (Ig) domains. MBP is also an abundant component. The extracellular Ig domains bind together the surfaces of

(a) Central nervous system neurons

(b) Peripheral nervous system neuron

▲ **FIGURE 23-14 Three types of glia cells.** (a) Astrocytes interact with neurons but do not insulate them. (b) Each Schwann cell insulates a section of a single peripheral nervous system axon. (c) A single oligodendrocyte can myelinate multiple CNS axons. [From B. Stevens,

2003, *Curr. Biol.* **13**:469, and adapted from D. L. Sherman and P. Brophy, 2005, *Nature Rev. Neurosci.* **6**:683–690, Photos: Courtesy of Varsha Shukla and Doug Field from NIH.]

sequential wraps around the axon to compact the spiral of myelin sheath (Figure 23-15b). Other proteins play this kind of role in the CNS.

 In humans, peripheral myelin, like CNS myelin, is a target of autoimmune disease, antibodies forming against P₀. The Guillain-Barre syndrome (GBS), also known as *acute inflammatory demyelinating polyneuropathy*, is one such disease. GBS is the most common cause of rapid-onset paralysis, occurring at a frequency of 10⁻⁵. The cause is unknown. The common inherited neurological disorder called *Charcot-Marie-Tooth disease*, which damages peripheral motor and sensory nerve function, is due to overexpression of the gene that encodes PMP22 protein, another constituent of peripheral nerve myelin. ■

Interactions between glia and neurons control the placement and spacing of myelin sheaths, and the assembly of nerve-transmission machinery at the nodes of Ranvier. Voltage-gated Na⁺ channels and Na⁺/K⁺ pumps, for example, congregate at the nodes of Ranvier through interactions with cytoskeletal proteins. While all the details of the node assembly process are not understood, a number of key players have been identified. In the PNS, where the process has been most studied, surface adhesion molecules in the Schwann cell membrane interact with neuronal adhesion molecules. The glial membrane immunoglobulin cell-adhesion molecule (IgCAM) called *neurofascin155* contacts two axonal proteins, contactin and contactin-associated protein at the edge of the node. These cell-cell contact events create boundaries at each side of the node.

▲ FIGURE 23-15 Formation and structure of a myelin sheath in the peripheral nervous system. (a) At high magnification the specialized spiral myelin (My) membrane appears as a series of layers, or lamellae, of phospholipid bilayers wrapped around the axon (Ax); Mit = mitochondrion. (b) Close up view of three layers of the myelin membrane spiral. The two most abundant membrane peripheral myelin proteins, P_0 and PMP22, are produced only by Schwann cells. The exoplasmic domain of a P_0 protein, which has an immunoglobulin fold, associates with similar domains emanating from P_0 proteins in the opposite membrane surface, thereby “zippering” together the exoplasmic membrane surfaces in close apposition. These interactions

are stabilized by binding of a tryptophan residue on the tip of the exoplasmic domain to lipids in the opposite membrane. Close apposition of the cytosolic faces of the membrane may result from binding of the cytosolic tail of each P_0 protein to phospholipids in the opposite membrane. PMP22 may also contribute to membrane compaction. Myelin basic protein (MBP), a cytosolic protein, remains between the closely apposed membranes as the cytosol is squeezed out. [Part (a) © Science VU/C, Raine/Visuals Unlimited; part (b) adapted from L. Shapiro et al., 1996, *Neuron* **17**:435, and E. J. Arroyo and S. S. Scherer, 2000, *Histochem. Cell Biol.* **113**:1.]

The channel proteins and other molecules that will accumulate at the node are initially dispersed through the axons. Then axonal proteins, including two IgCAMs called *NrCAM* and *neurofascin186*, as well as ankyrin G (Chapter 17), accumulate within the node. The two IgCAMs bind to a single transmembrane domain protein called *gliomedin* that is expressed in the glial cell. Experiments that eliminated gliomedin production showed that without it nodes do not form, so it is a key regulator. Ankyrin in the node contacts β IV spectrin, a major constituent of the cytoskeleton, thus tethering the node’s protein complex to the cytoskeleton. Na^+ channels become associated with neurofascin186, *NrCAM*, and ankyrin G, firmly trapping the channel where it is needed. As a result of these multiple protein-protein interactions, the concentration of Na^+ channels is roughly a hundredfold higher in the nodal membrane of myelinated axons than in the axonal membrane of nonmyelinated neurons.

Astrocytes The third type of glial cell is the astrocyte, named for its starlike shape (see Figure 23-14a). These can constitute more than a third of brain mass and half of the brain’s cells. There are two kinds. *Protoplasmic astrocytes* are in the gray matter (the areas rich in cell bodies); *fibrous astrocytes* are in the white matter (the areas composed mainly of axons; it is the myelin that makes it look white). The astrocytes make long thin processes that envelop all the brain’s blood vessels.

Astrocytes are critical regulators of the formation of the blood-brain barrier. A mass of blood vessels in the brain supplies oxygen and removes CO_2 , and delivers glucose and amino acids, with capillaries within a few micrometers of every cell. These capillaries form the blood-brain barrier, which prevents, for example, blood-borne circulating neurotransmitters and some drugs from entering the brain. The barrier consists of a set of tight junctions (Chapter 19) made by the endothelial cells that form the walls of capillaries. Astrocytes promote specialization of these endothelial cells, making them less permeable (Figure 23-16).

Many synapses and dendrites are also surrounded by astrocyte processes. Astrocytes produce abundant extracellular matrix proteins, some of which are used as guidance cues by migrating neurons, and a host of growth factors that carry a variety of types of information to neurons. The Ca^{2+} , K^+ , Na^+ , and Cl^- channels, among others, found in the plasma membranes of astrocytes influence the concentration of free ions in the extracellular space, thus affecting the membrane potentials of neurons and of the astrocytes themselves. Astrocytes also take up glutamate, a neurotransmitter, from extracellular spaces and turn it into glutamine. When nearby neurons have fired, glutamate binds to glutamate receptors on astrocytes, enabling the astrocytes to sense the event. Astrocytes are joined to each other by gap junctions, so changes in ionic composition in any of them are communicated to others, over distances of hundreds of microns.

◀ **FIGURE 23-16 Astrocytes interact with endothelial cells at the blood-brain barrier.** The purpose of the blood-brain barrier is to control what types of molecules can travel out of the bloodstream into the brain and vice versa. The formation of the barrier by the endothelial cells that make up blood vessel walls entering the brain is directed by surrounding astrocytes. Capillaries in the brain are formed by endothelial cells with tight junctions that are impermeable to most molecules. Transport between cells is blocked, so only small molecules that can diffuse or substances specifically transported through cells can cross the barrier. The endothelial cells have transporters and permeability characteristics that allow oxygen and CO₂ across but selectively prevent other substances from crossing. Astrocytes surround the blood vessels, in contact with the endothelial cells, and send secreted protein signals to induce the endothelial cells to produce a selective barrier. Unless there is a specific carrier involved, lipid-soluble molecules stand the best chance of getting across, though they may travel poorly in the blood. Electrolytes, like Na⁺ and Cl⁻, are moved across by specific channel and transport proteins. The brain's endothelial cells have less vesicle transport than most endothelial cells, presumably since transport is more selective. The endothelial cells (burgundy) are ensheathed by a layer of basal lamina (orange) and contacted on the outside by astrocyte processes (tan). Pericytes are mesenchymal cells that provide support to the capillaries. [From N. J. Abbott, L. Rönnbäck, and E. Hansson, 2006, *Nature Rev. Neurosci.* 7:41–53.]

KEY CONCEPTS OF SECTION 23.2

Voltage-Gated Ion Channels and the Propagation of Action Potentials in Nerve Cells

- Action potentials are sudden membrane depolarizations followed by a rapid repolarization. They originate at the axon initial segment and move down the axon toward the axon terminals, where the electric impulse is transmitted to other cells via a synapse (see Figures 23-3 and 23-6).
- An action potential results from the sequential opening and closing of voltage-gated Na⁺ and K⁺ channels in the plasma membrane of neurons and muscle cells (see Figure 23-9).
- Opening of voltage-gated Na⁺ channels permits influx of Na⁺ ions for about 1 ms, causing a sudden large depolarization of a segment of the membrane. The channels then close and become unable to open (refractory) for several milliseconds, preventing further Na⁺ flow (see Figure 23-7).

- As the action potential reaches its peak, opening of voltage-gated K⁺ channels permits efflux of K⁺ ions, which repolarizes and then hyperpolarizes the membrane. As these channels close, the membrane returns to its resting potential (see Figure 23-3).
- The excess cytosolic cations associated with an action potential generated at one point on an axon spread passively to the adjacent segment, triggering opening of voltage-gated Na⁺ channels and movement of the action potential along the axon.
- Because of the absolute refractory period of the voltage-gated Na⁺ channels and the brief hyperpolarization resulting from K⁺ efflux, the action potential is propagated in one direction only, toward the axon terminus.
- Voltage-gated Na⁺ and Ca²⁺ channels are monomeric proteins containing four domains that are structurally and functionally similar to each of the subunits in the tetrameric voltage-gated K⁺ channels.
- Each domain or subunit in voltage-gated cation channels contains six transmembrane α helices and a nonhelical P segment that forms the ion-selectivity pore (see Figure 23-10).
- Opening of voltage-gated channels results from movement of the positively charged S4 α helices toward the extracellular side of the membrane in response to a depolarization of sufficient magnitude.
- Closing and inactivation of voltage-gated cation channels result from movement of a cytosolic segment into the open pore (see Figure 23-11c).
- Myelination, which increases the rate of impulse conduction up to a hundredfold, permits the close packing of neurons characteristic of vertebrate brains.

- In myelinated neurons, voltage-gated Na^+ channels are concentrated at the nodes of Ranvier. Depolarization at one node spreads rapidly with little attenuation to the next node, so that the action potential jumps from node to node (see Figure 23-13).
- Myelin sheaths are produced by glial cells that wrap themselves in spirals around neurons. Oligodendrocytes produce myelin for the CNS; Schwann cells, for the PNS (see Figure 23-14).
- Astrocytes, a third type of glial cell, wrap their processes around synapses and blood vessels. Astrocytes secrete proteins that stimulate synapse formation, and also induce the endothelial cells of blood vessels to produce a blood-brain barrier that limits transepithelial flow of substances (see Figure 23-16).

23.3 Communication at Synapses

As we have discussed, electrical pulses transmit signals along neurons, but signals are transmitted between neurons and other excitable cells by chemical signals. Synapses are the junctions where *presynaptic* neurons release these chemical signals, or neurotransmitters, that act on a *postsynaptic* target cell (Figure 23-4), which can be another neuron or a muscle or gland cell. Neurotransmitters are small, water-soluble molecules (e.g., acetylcholine, dopamine). The cell-cell communication at chemical synapses goes in one direction: pre- to postsynaptic cell. Arrival of an action potential at an axon terminal leads to opening of voltage-sensitive Ca^{2+} channels and an influx of Ca^{2+} , causing a localized rise in the cytosolic Ca^{2+} concentration in the axon terminus. The rise in Ca^{2+} in turn triggers fusion of small (40–50-nm) synaptic vesicles containing neurotransmitters with the plasma membrane, releasing neurotransmitters from this presynaptic cell into the synaptic cleft, the narrow space separating it from postsynaptic cells. The membrane of the postsynaptic cell is located within approximately 50 nm of the presynaptic membrane.

Neurotransmitter receptors fall into two broad classes: ligand-gated ion channels, which open immediately upon neurotransmitter binding, and G protein-coupled receptors. Neurotransmitter binding to a G protein-coupled receptor induces the opening or closing of a *separate* ion-channel protein over a period of seconds to minutes. These “slow” neurotransmitter receptors are discussed in Chapter 15 along with G protein-coupled receptors that bind different types of ligands and modulate the activity of cytosolic proteins other than ion channels. Here we examine the structure and operation of the *nicotinic acetylcholine receptor* found at many nerve-muscle synapses. It was the first ligand-gated ion channel to be purified, cloned, and characterized at the molecular level, and provides a paradigm for other neurotransmitter-gated ion channels.

The duration of the neurotransmitter signal depends on the amount of transmitter released by the presynaptic cell, which in turn depends on the amount of transmitter that

had been stored and upon the frequency of action potentials arriving at the synapse. The duration of signal also depends on how rapidly any remaining neurotransmitter is retrieved by the presynaptic cell. Presynaptic cell plasma membranes, as well as glia, contain transporter proteins that pump neurotransmitters across the plasma membrane back into the cell, thus keeping the extracellular concentrations of transmitter low.

Here we focus first on how synapses form and how they control the regulated secretion of neurotransmitters in the context of the basic principles of vesicular trafficking outlined in Chapter 14. Next we look at the mechanisms that limit the duration of the synaptic signal, and how neurotransmitters are received and interpreted by the postsynaptic cell.

Formation of Synapses Requires Assembly of Presynaptic and Postsynaptic Structures

Axons extend from the cell body during development, guided by signals from other cells along the way so that the axon termini will reach the correct location (see Section 23.5). As axons grow, they come into contact with the dendrites of other neurons, and often at such sites synapses form. In the CNS, synapses with presynaptic specializations occur frequently all along an axon, in contrast to motor neurons, which form synapses with muscle cells only at the axon termini.

Neurons cultured in isolation will not form synapses very efficiently, but when glia are added, the rate of synapse formation increases substantially. Astrocytes and Schwann cells send signals to neurons to stimulate the formation of synapses and then help to preserve them (Figure 23-17). To

▲ **EXPERIMENTAL FIGURE 23-17** Signals from astrocytes have been shown to induce synapse formation. Immunostaining for the presynaptic protein synaptotagmin (red) and the postsynaptic protein PSD-95 (yellow) yields few measured puncta (dots of stain) in control retinal ganglion cells cultured in the absence of astrocytes (*left*). However, a 3–5-fold increase in puncta occurs when these cells are cultured in the presence of astrocytes or the astrocyte protein product thrombospondin (*right*). (rTSP2 = the recombinant thrombospondin 2 that was used). Astrocytes secrete thrombospondin, which by itself has much the same effect on synapse formation as astrocytes themselves. Scale bar is 30 μm . [Reproduced with permission from K. S. Christopherson et al., 2005, *Cell* 120:421–433.]

discover the signals involved, culture medium in which glia had been incubated was added to neuron cultures, and synapse formation was stimulated. By purifying different substances from that medium it was possible to identify the signal. Thrombospondin (TSP) protein, a component of extracellular matrix, was found to be the active agent. Confirmation came from mice lacking two *thrombospondin* genes: the mice had only 70 percent of the normal number of synapses in their brains. TSP probably does not work alone, as it is not as potent in inducing synapses as are whole glia. Another molecule that appears to account for some of the synapse-inducing activity of glia is cholesterol, and direct contact between glia and neurons may contribute as well.

Mutual communication between neurons and the glia that surround them is frequent and complex. The signals and information they carry is an area of active research. There is even evidence that neurons form synapses on glia. While glia do not have action potentials, they do have complex arrays of channels and ion fluxes.

At the site of a synapse, the presynaptic cell has hundreds to thousands of synaptic vesicles, some docked at the membrane and others waiting in reserve. The release into the synaptic cleft occurs in the *active zone*, a specialized region of the plasma membrane containing a remarkable assemblage of proteins whose functions include modifying the properties of the synaptic vesicles and bringing them into position for docking and fusing with the plasma membrane. Viewed by electron microscopy, the active zone has electron-dense material and fine cytoskeletal filaments (Figure 23-18). The active zone is assembled gradually, with synaptic vesicles accumulating first, then cytoskeletal elements, and then other proteins. A similarly dense region of specialized structures is seen across the synapse in the postsynaptic cell, the *postsynaptic density (PSD)*. Cell-adhesion molecules that connect pre- and postsynaptic cells keep the active zone and PSD aligned. After release of synaptic vesicles in response to an action potential, the presynaptic neuron retrieves synaptic vesicle membrane proteins by *endocytosis* both within and outside the active zone.

The induction of PSD assembly has been extensively studied at the *neuromuscular junction (NMJ)*. At these synapses *acetylcholine* is the neurotransmitter produced by motor neurons, and its receptor, AChR, is produced by the postsynaptic cell, which is a muscle cell. Muscle cell precursors, myoblasts, put into culture will spontaneously fuse into multinucleate myotubes that look similar to normal muscle cells (Chapter 21). As myotubes form, AChR is produced and inserted into the plasma membrane of the myotubes, reaching a density of about 1000 receptors/ μm^2 . The AChR is dispersed through the membrane, but if neurons are added to the culture, the AChR starts to concentrate at points of contact with the neurons. The neurons cause movement of preexisting AChR and also induce the myotubes to produce additional AChR. The density of receptors in a mature synapse reaches about 10,000–20,000/ μm^2 , while elsewhere in the plasma membrane the density is $<10/\mu\text{m}^2$.

These observations led to an investigation of the mutual signaling by neurons and myotubes. The conclusion from

▲ **FIGURE 23-18 Synaptic vesicles in the axon terminal near the region where neurotransmitter is released.** In this longitudinal section through a neuromuscular junction, the basal lamina lies in the synaptic cleft separating the neuron from the muscle membrane, which is extensively folded. Acetylcholine receptors are concentrated in the postsynaptic muscle membrane at the top and part way down the sides of the folds in the membrane. A Schwann cell surrounds the axon terminal. [From J. E. Heuser and T. Reese, 1977, in E. R. Kandel, ed., *The Nervous System*, vol. 1, *Handbook of Physiology*, Williams and Wilkins, p. 266.]

this work is that muscle cells begin to organize their postsynaptic structures before there is any discernible influence of motor axons. The arrival of an axon stabilizes and further modifies the structures that have formed.

Neurotransmitters Are Transported into Synaptic Vesicles by H⁺-Linked Antiport Proteins

In this section, we focus on how neurotransmitters are packaged in membrane-bound *synaptic vesicles* in the axon terminus. Numerous small molecules function as neurotransmitters at various synapses. With the exception of acetylcholine, the neurotransmitters shown in Figure 23-19 are amino acids or derivatives of amino acids. Nucleotides such as ATP and the corresponding nucleosides, which lack phosphate groups, also function as neurotransmitters. Each neuron generally produces just one type of neurotransmitter.

All the “classic” neurotransmitters are synthesized in the cytosol and imported into membrane-bound synaptic vesicles within axon terminals, where they are stored. These vesicles are 40–50 nm in diameter, and their lumen has a low pH, generated by operation of a V-class proton pump in the vesicle membrane. Similar to the accumulation of metabolites

The three transmitters synthesized from tyrosine, which contain the catechol moiety (blue highlight), are referred to as *catecholamines*.

in plant vacuoles (see Figure 11-28), this proton concentration gradient (vesicle lumen > cytosol) powers neurotransmitter import by ligand-specific H^+ -linked antiporters in the vesicle membrane.

For example, acetylcholine is synthesized from acetyl coenzyme A (acetyl CoA), an intermediate in the degradation of glucose and fatty acids, and choline in a reaction catalyzed by choline acetyltransferase:

Synaptic vesicles take up and concentrate acetylcholine from the cytosol against a steep concentration gradient, using an H^+ /acetylcholine antiporter in the vesicle membrane. Curiously, the gene encoding this antiporter is contained entirely within the first intron of the gene encoding choline acetyltransferase, a mechanism conserved throughout evolution for ensuring coordinate expression of these two proteins. Different H^+ /neurotransmitter antiport proteins are used for import of other neurotransmitters into synaptic vesicles.

Synaptic Vesicles Loaded with Neurotransmitter Are Localized near the Plasma Membrane

Neurotransmitters are synthesized by enzymes in the cytosol and then transported into synaptic vesicles by transporter proteins dedicated to the task. For example glutamate is imported into synaptic vesicles by proteins called *vesicular glutamate transporters (VGLUTs)*. VGLUTs are highly specific for glutamate but have rather low substrate affinity ($K_m = 1\text{--}3\text{mM}$). The transporters are antiporters, moving glutamate into synaptic vesicles while protons move in the other direction. The membrane-potential gradient that drives the transport process is established by a vacuolar-type ATPase (Chapter 11).

The **exocytosis** of neurotransmitters from synaptic vesicles involves targeting and fusion events similar to those that lead to release of secreted proteins in the secretory pathway (Figure 23-20). However, several unique features permit the very rapid release of neurotransmitters in response to arrival of an action potential at the presynaptic axon terminal. For example, in resting neurons some neurotransmitter-filled synaptic vesicles are “docked” at the plasma membrane; others are in reserve in the active zone near the plasma membrane at the synaptic cleft.

▲ FIGURE 23-20 Cycling of neurotransmitters and of synaptic vesicles in axon terminals. Most synaptic vesicles are formed by endocytic recycling as depicted here. The entire cycle typically takes about 60 seconds. Step **1**: The uncoated vesicles employ a variety of antiporters (blue) and other transport proteins (green) to import neurotransmitters (red dots) from the cytosol. Step **2**: Synaptic vesicles loaded with neurotransmitter move to the active zone. Step **3**: Vesicles dock at defined sites on the plasma membrane of a presynaptic cell. Synaptotagmin prevents membrane fusion and release of neurotransmitter. Botulinum toxin prevents exocytosis by proteolytically cleaving VAMP, the v-SNARE on vesicles. Synaptotagmin does not participate in steps **4–6** or **1**, though it is still present. For simplicity, it is not shown. Step **4**: In response to a nerve impulse (action potential), voltage-gated Ca²⁺ channels in the plasma membrane open, allowing an influx of Ca²⁺ from the extracellular

In addition, the membrane of synaptic vesicles contains a specialized Ca²⁺-binding protein that senses the rise in cytosolic Ca²⁺ after arrival of an action potential, triggering rapid fusion of docked vesicles with the presynaptic membrane.

A highly organized arrangement of cytoskeletal fibers in the axon terminal helps localize synaptic vesicles in the active zone. The vesicles themselves are linked together by *synapsin*, a fibrous phosphoprotein associated with the cytosolic surface of all synaptic-vesicle membranes. Filaments of synapsin also radiate from the plasma membrane and bind to vesicle-associated synapsin. These interactions probably keep synap-

tic vesicles close to the part of the plasma membrane facing the synapse. Indeed, synapsin knockout mice, although viable, are prone to seizures; during repetitive stimulation of many neurons in such mice, the number of synaptic vesicles that fuse with the plasma membrane is greatly reduced. Thus synapsin are thought to recruit synaptic vesicles to the active zone.

Rab3A, a GTP-binding protein located in the membrane of synaptic vesicles, is also required for targeting of neurotransmitter-filled vesicles to the active zone of presynaptic cells facing the synaptic cleft. Rab3A knockout mice, like synapsin-deficient mice, exhibit a reduced number of synaptic

vesicles able to fuse with the plasma membrane after repetitive stimulation. The neuron-specific Rab3 is similar in sequence and function to other Rab proteins that participate in docking vesicles on particular target membranes in the secretory pathway.

Influx of Ca^{2+} Triggers Release of Neurotransmitters

The exocytosis of neurotransmitters from synaptic vesicles involves vesicle-targeting and fusion events similar to those that occur during the intracellular transport of secreted and plasma-membrane proteins (Chapter 13). Two features critical to synapse function differ from other secretory pathways: (1) secretion is tightly coupled to arrival of an action potential at the axon terminus, and (2) synaptic vesicles are recycled locally to the axon terminus after fusion with the plasma membrane. Figure 23-20 shows the entire cycle whereby synaptic vesicles are filled with neurotransmitter, release their contents, and are recycled.

Depolarization of the plasma membrane cannot, by itself, cause synaptic vesicles to fuse with the plasma membrane. In order to trigger vesicle fusion, an action potential must be converted into a chemical signal—namely, a localized rise in the cytosolic Ca^{2+} concentration. The transducers of the electric signals are *voltage-gated Ca^{2+} channels* localized to the region of the plasma membrane adjacent to the synaptic vesicles. The membrane depolarization due to arrival of an action potential opens these channels, permitting an influx of Ca^{2+} ions from the extracellular medium into the axon terminal.

A simple experiment demonstrates the importance of voltage-gated Ca^{2+} channels in release of neurotransmitters. A preparation of neurons in a Ca^{2+} -containing medium is treated with tetrodotoxin, a drug that blocks voltage-gated Na^+ channels and thus prevents conduction of action potentials. As expected, no neurotransmitters are secreted into the culture medium. If the axonal membrane then is artificially depolarized by making the medium ≈ 100 mM KCl in the presence of extracellular Ca^{2+} , neurotransmitters are released from the cells because of the influx of Ca^{2+} through open voltage-gated Ca^{2+} channels. Indeed, patch-clamping experiments show that voltage-gated Ca^{2+} channels, like voltage-gated Na^+ channels, open transiently upon depolarization of the membrane.

Two pools of neurotransmitter-filled synaptic vesicles are present in axon terminals: those docked at the plasma membrane, which can be readily exocytosed, and those in reserve in the active zone near the plasma membrane. Each rise in Ca^{2+} triggers exocytosis of about 10 percent of the docked vesicles. Membrane proteins unique to synaptic vesicles then are specifically internalized by endocytosis, usually via the same types of clathrin-coated vesicles used to recover other plasma-membrane proteins by other types of cells. After the endocytosed vesicles lose their clathrin coat, they are rapidly refilled with neurotransmitter. The ability of many neurons to fire 50 times a second is clear evidence that the recycling of vesicle membrane proteins occurs quite rapidly. The ma-

chinery of endocytosis and exocytosis is highly conserved, and is explained extensively in Chapter 14.

A Calcium-Binding Protein Regulates Fusion of Synaptic Vesicles with the Plasma Membrane

Fusion of synaptic vesicles with the plasma membrane of axon terminals depends on SNAREs, the same type of proteins that mediate membrane fusion of other regulated secretory vesicles (Figure 23-20). The principal v-SNARE in synaptic vesicles (VAMP) tightly binds syntaxin and SNAP-25, the principal t-SNAREs in the plasma membrane of axon terminals, to form four-helix SNARE complexes. After fusion, SNAP proteins and NSF within the axon terminal promote disassociation of VAMP from t-SNAREs, as in the fusion of secretory vesicles depicted previously (Figure 14-10).

 Strong evidence for the role of VAMP in neurotransmitter exocytosis is provided by the mechanism of action of botulinum toxin, a bacterial protein that can cause the paralysis and death characteristic of *botulism*, a type of food poisoning. The toxin is composed of two polypeptides: One binds to motor neurons that release acetylcholine at synapses with muscle cells, facilitating entry of the other polypeptide, a protease, into the cytosol of the axon terminal. The only protein this protease cleaves is VAMP (see Figure 23-20). After the botulinum protease enters an axon terminal, synaptic vesicles that are not already docked rapidly lose their ability to fuse with the plasma membrane because cleavage of VAMP prevents assembly of SNARE complexes. The resulting block in acetylcholine release at neuromuscular synapses causes paralysis. However, vesicles that are already docked exhibit remarkable resistance to the toxin, indicating that SNARE complexes may already be in a partially assembled, protease-resistant state when vesicles are docked on the presynaptic membrane. ■

The signal that triggers exocytosis of docked synaptic vesicles is a rise in the Ca^{2+} concentration in the cytosol near vesicles from <0.1 μM , characteristic of resting cells, to 1–100 μM following arrival of an action potential in stimulated cells. The speed with which synaptic vesicles fuse with the presynaptic membrane after a rise in cytosolic Ca^{2+} (less than 1 ms) indicates that the fusion machinery is entirely assembled in the resting state and can rapidly undergo a conformational change leading to exocytosis of neurotransmitter. A Ca^{2+} -binding protein called *synaptotagmin*, located in the membrane of synaptic vesicles, is thought to be a key component of the vesicle-fusion machinery that triggers exocytosis in response to Ca^{2+} (see Figure 23-20).

Several lines of evidence support a role for synaptotagmin as the Ca^{2+} sensor for exocytosis of neurotransmitters. Mutant embryos of *Drosophila* and *C. elegans* that completely lack synaptotagmin fail to hatch and exhibit very reduced, uncoordinated muscle contractions. Larvae with partial loss-of-function mutations of synaptotagmin survive, but their neurons are defective in Ca^{2+} -stimulated vesicle exocytosis. Moreover, in mice, mutations in synaptotagmin that decrease its affinity

for Ca^{2+} cause a corresponding increase in the amount of cytosolic Ca^{2+} needed to trigger rapid exocytosis. The precise mechanism of synaptotagmin function is still unresolved.

Signaling at Synapses Is Terminated by Degradation or Reuptake of Neurotransmitters

Following their release from a presynaptic cell, neurotransmitters must be removed or destroyed to prevent continued stimulation of the postsynaptic cell. Signaling can be terminated by diffusion of a transmitter away from the synaptic cleft, but this is a slow process. Instead, one of two more rapid mechanisms terminates the action of neurotransmitters at most synapses.

Signaling by acetylcholine is terminated when it is hydrolyzed to acetate and choline by *acetylcholinesterase*, an enzyme localized to the synaptic cleft. Choline released in this reaction is transported back into the presynaptic axon terminal by a Na^+ /choline symporter and used in synthesis of more acetylcholine. The operation of this transporter is similar to that of the Na^+ -linked symporters used to transport glucose into cells against a concentration gradient (see Figure 11-25).

With the exception of acetylcholine, all the neurotransmitters shown in Figure 23-19 are removed from the synaptic cleft by transport into the axon terminals that released them. Thus these transmitters are recycled intact, as depicted in Figure 23-20 (step 5). Transporters for GABA, norepinephrine, dopamine, and serotonin were the first to be cloned and studied. These four transport proteins are all Na^+ -linked symporters. They are 60–70 percent identical in their amino acid sequences, and each is thought to contain 12 transmembrane α helices. As with other Na^+ symporters, the movement of Na^+ into the cell down its electrochemical gradient provides the energy for uptake of the neurotransmitter. To maintain electroneutrality, Cl^- often is transported via an ion channel along with the Na^+ and neurotransmitter.

Neurotransmitters and their transporters are targets of a variety of powerful and sometimes devastating drugs. Cocaine inhibits the transporters for norepinephrine, serotonin, and dopamine. Binding of cocaine to the dopamine transporter inhibits reuptake of dopamine, thus prolonging signaling at key brain synapses; indeed, the dopamine transporter is the principal brain “cocaine receptor.” Therapeutic agents such as the antidepressant drugs fluoxetine (Prozac) and imipramine block serotonin uptake, and the tricyclic antidepressant desipramine blocks norepinephrine uptake. ■

Fly Mutants Lacking Dynamin Cannot Recycle Synaptic Vesicles

Synaptic vesicles are formed primarily by endocytic budding from the plasma membrane of axon terminals. Endocytosis usually involves clathrin-coated pits and is quite specific, in that several membrane proteins unique to the synaptic vesicles (e.g., neurotransmitter transporters) are specifically incorporated into the endocytosed vesicles. In this way, synaptic-

vesicle membrane proteins can be reused and the recycled vesicles refilled with neurotransmitter (see Figure 23-20).

As in the formation of other clathrin/AP-coated vesicles, pinching off of endocytosed synaptic vesicles requires the GTP-binding protein *dynamin* (see Figure 14-19). Indeed, analysis of a temperature-sensitive *Drosophila* mutant called *shibire* (*shi*), which encodes the fly dynamin protein, provided early evidence for the role of dynamin in endocytosis. At the permissive temperature of 20 °C, the mutant flies are normal, but at the nonpermissive temperature of 30 °C, they are paralyzed (*shibire*, “paralyzed,” in Japanese) because pinching off of clathrin-coated pits in neurons and other cells is blocked. When viewed in the electron microscope, the *shi* neurons at 30 °C show abundant clathrin-coated pits with long necks but few clathrin-coated vesicles. The appearance of nerve terminals in *shi* mutants at the nonpermissive temperature is similar to that of terminals from normal neurons incubated in the presence of a nonhydrolyzable analog of GTP (see Figure 14-20). Because of their inability to pinch off new synaptic vesicles, the neurons in *shi* mutants eventually become depleted of synaptic vesicles when flies are shifted to the nonpermissive temperature, leading to a cessation of synaptic signaling and to paralysis.

Opening of Acetylcholine-Gated Cation Channels Leads to Muscle Contraction

In this section we look at how binding of neurotransmitters by receptors on postsynaptic cells leads to changes in their membrane potential, using the communication between motor neurons and muscles as an example. At these synapses, often called neuromuscular junctions, acetylcholine is the neurotransmitter. A single axon terminus of a frog motor neuron may contain a million or more synaptic vesicles, each containing 1000–10,000 molecules of acetylcholine; these vesicles often accumulate in rows in the active zone (see Figure 23-18). Such a neuron can form synapses with a single skeletal muscle cell at several hundred points.

The nicotinic acetylcholine receptor, which is expressed in muscle cells, is a *ligand-gated channel* that admits both K^+ and Na^+ . These receptors are also produced in the brain and are important in learning and memory; acetylcholine receptor loss is observed in schizophrenia, epilepsy, drug addiction, and Alzheimer’s disease. Antibodies against acetylcholine receptors constitute a major part of the autoimmune reactivity in the disease myasthenia gravis. The receptor is so named because it is bound by nicotine; it has been implicated in addiction to nicotine by tobacco smokers. The receptor is also the target of potent neurotoxins, such as the conotoxins produced by certain Pacific Ocean snails. There are at least 14 different isoforms of the receptor, which assemble into homo- and heteropentamers with varied properties.

The effect of acetylcholine on this receptor can be determined by patch-clamping studies on isolated outside-out patches of muscle plasma membranes (see Figure 11-21c). Such measurements have shown that acetylcholine causes opening of a cation channel in the receptor capable of transmitting 15,000–30,000 Na^+ or K^+ ions per millisecond.

▲ FIGURE 23-21 Sequential activation of gated ion channels at a neuromuscular junction. Arrival of an action potential at the terminus of a presynaptic motor neuron induces opening of voltage-gated Ca^{2+} channels (step **1**) and subsequent release of acetylcholine, which triggers opening of the ligand-gated acetylcholine receptors in the muscle plasma membrane (step **2**). The open channel allows an influx of Na^+ and an efflux of K^+ . The Na^+ influx produces a localized depolarization of the membrane, leading to opening of voltage-gated Na^+ channels and generation of an action potential (step **3**). When the spreading depolarization reaches T tubules, it is sensed by voltage-gated Ca^{2+} channels in the plasma membrane. Through an unknown mechanism (indicated as ?) these channels remain closed but influence Ca^{2+} channels in the sarcoplasmic reticulum membrane (a network of membrane-bound compartments in muscle), releasing stored Ca^{2+} into the cytosol (step **4**). The resulting rise in cytosolic Ca^{2+} causes muscle contraction by mechanisms discussed in Chapter 17.

However, since the resting potential of the muscle plasma membrane is near E_{K} , the potassium equilibrium potential, opening of acetylcholine receptor channels causes little increase in the efflux of K^+ ions; Na^+ ions, on the other hand, flow into the muscle cell, driven by the Na^+ electrochemical gradient.

The simultaneous increase in permeability to Na^+ and K^+ ions following binding of acetylcholine produces a net depolarization to about -15 mV from the muscle resting potential of -85 to -90 mV. As shown in Figure 23-21, this localized depolarization of the muscle plasma membrane triggers opening of voltage-gated Na^+ channels, leading to generation and conduction of an action potential in the muscle cell surface membrane by the same mechanisms described previously for neurons. When the membrane depolarization reaches T tubules, specialized invaginations of the plasma membrane, it affects Ca^{2+} channels in the plasma membrane apparently without causing them to open. Somehow this causes opening of adjacent Ca^{2+} -release channels in the sarcoplasmic reticulum membrane. The subsequent flow of stored Ca^{2+} ions from the sarcoplasmic reticulum into the cytosol raises the cytosolic Ca^{2+} concentration sufficiently to induce muscle contraction.

Careful monitoring of the membrane potential of the muscle membrane at a synapse with a cholinergic motor neuron

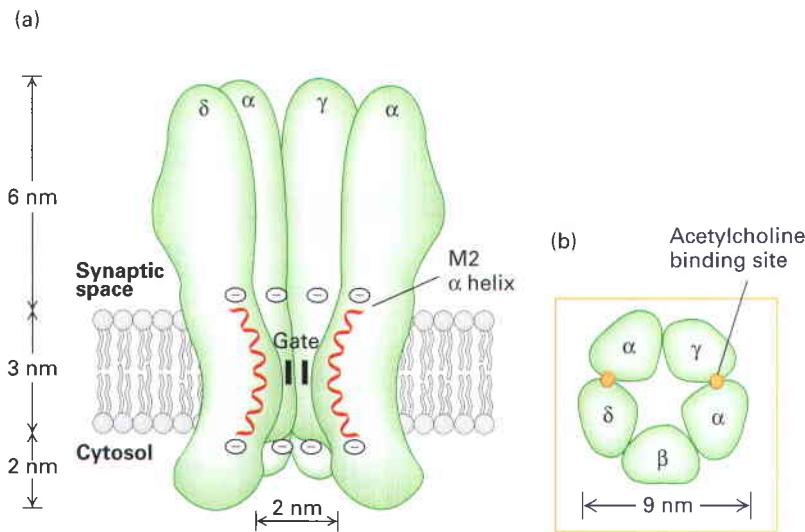

has demonstrated spontaneous, intermittent, and random ≈ 2 -ms depolarizations of about 0.5 – 1.0 mV in the absence of stimulation of the motor neuron. Each of these depolarizations is caused by the spontaneous release of acetylcholine from a single synaptic vesicle. Indeed, demonstration of such spontaneous small depolarizations led to the notion of the quantal release of acetylcholine (later applied to other neurotransmitters) and thereby led to the hypothesis of vesicle exocytosis at synapses. The release of one acetylcholine-containing synaptic vesicle results in the opening of about 3000 ion channels in the postsynaptic membrane, far short of the number needed to reach the threshold depolarization that induces an action potential. Clearly, stimulation of muscle contraction by a motor neuron requires the nearly simultaneous release of acetylcholine from numerous synaptic vesicles.

All Five Subunits in the Nicotinic Acetylcholine Receptor Contribute to the Ion Channel

The acetylcholine receptor from skeletal muscle is a pentameric protein with a subunit composition of $\alpha_2\beta\gamma\delta$. The α , β , γ , and δ subunits have considerable sequence homology; on average, about 35–40 percent of the residues in any two subunits are similar. The complete receptor has fivefold symmetry, and the actual cation channel is a tapered central pore lined by homologous segments from each of the five subunits (Figure 23-22).

The channel opens when the receptor cooperatively binds two acetylcholine molecules to sites located at the interfaces of the $\alpha\delta$ and $\alpha\gamma$ subunits. Once acetylcholine is bound to a receptor, the channel is opened within a few microseconds. Studies measuring the permeability of different small cations suggest that the open ion channel is, at its narrowest, about 0.65 – 0.80 nm in diameter, in agreement with estimates from electron micrographs. This would be sufficient to allow passage of both Na^+ and K^+ ions with their shell of bound water molecules. Thus the acetylcholine receptor probably transports hydrated ions, unlike Na^+ and K^+ channels, both of which allow passage only of nonhydrated ions (see Figure 11-20).

The central ion channel is lined by five homologous transmembrane M2 α helices, one from each of the five subunits (see Figure 23-22a). The M2 helices are composed largely of hydrophobic or uncharged polar amino acids, but negatively charged aspartate or glutamate residues are located at each end, near the membrane faces, and several serine or threonine residues are near the middle. Mutant acetylcholine receptors in which a single negatively charged glutamate or aspartate in one M2 helix is replaced by a positively charged lysine have been expressed in frog oocytes. Patch-clamping measurements indicate that such altered proteins can function as channels, but the number of ions that pass through during the open state is reduced. The greater the number of glutamate or aspartate residues mutated (in one or multiple M2 helices), the greater the reduction in ion conductivity. These findings suggest that aspartate and glutamate residues form a ring of negative charges on the external surface of the pore that help to screen out anions and attract Na^+ or K^+ ions as they enter the channel. A similar ring of negative charges lining the cytosolic pore surface also helps select cations for passage (see Figure 23-22).

◀ **FIGURE 23-22 Three-dimensional structure of the nicotinic acetylcholine receptor.** (a) Schematic cutaway model of the pentameric receptor in the membrane; for clarity, the β subunit is not shown. Each subunit contains an M2 α helix (red) that faces the central pore. Aspartate and glutamate side chains at both ends of the M2 helices form two rings of negative charges that help exclude anions from and attract cations to the channel. The gate, which is opened by binding of acetylcholine, lies within the pore. (b) Cross section of the exoplasmic face of the receptor showing the arrangement of subunits around the central pore. The two acetylcholine binding sites are located about 3 nm from the membrane surface.

The two acetylcholine binding sites in the extracellular domain of the receptor lie ≈ 4 to 5 nm from the center of the pore. Binding of acetylcholine thus must trigger conformational changes in the receptor subunits that can cause channel opening at some distance from the binding sites. Receptors in isolated postsynaptic membranes can be trapped in the open or closed state by rapid freezing in liquid nitrogen. Images of such preparations suggest that the five M2 helices rotate relative to the vertical axis of the channel during opening and closing.

We have discussed the neuromuscular junction as an excellent example of how neurotransmitters and their receptors work. Similar ideas apply to glutamate and GABA, the two principal neurotransmitters in vertebrate brain. They use ligand-gated channels that work along the same principles as AchR.

Nerve Cells Make an All-or-None Decision to Generate an Action Potential

At the neuromuscular junction, virtually every action potential in the presynaptic motor neuron triggers an action potential in the postsynaptic muscle cell that propagates along the muscle fiber. The situation at synapses between neurons, especially those in the brain, is much more complex because the postsynaptic neuron commonly receives signals from many presynaptic neurons. The neurotransmitters released from presynaptic neurons may bind to an *excitatory receptor* on the postsynaptic neuron, thereby opening a channel that admits Na^+ ions or both Na^+ and K^+ ions. The acetylcholine receptor just discussed is one of many excitatory receptors, and opening of such ion channels leads to depolarization of the postsynaptic plasma membrane, promoting generation of an action potential. In contrast, binding of a neurotransmitter to an *inhibitory receptor* on the postsynaptic cell causes opening of K^+ or Cl^- channels, leading to an efflux of additional K^+ ions from the cytosol or an influx of Cl^- ions. In either case, the ion flow tends to hyperpolarize the plasma membrane, which inhibits generation of an action potential in the postsynaptic cell.

A single neuron can be affected simultaneously by signals received at multiple excitatory and inhibitory synapses. The

neuron continuously integrates these signals and determines whether or not to generate an action potential. In this process, the various small depolarizations and hyperpolarizations generated at synapses move along the plasma membrane from the dendrites to the cell body and then to the axon initial segment, where they are summed together. An action potential is generated whenever the membrane at the axon initial segment becomes depolarized to a certain voltage called the *threshold potential* (Figure 23-23). Thus an action potential is generated in an all-or-nothing fashion: depolarization to the threshold always leads to an action potential, whereas any depolarization that does not reach the threshold potential never induces it.

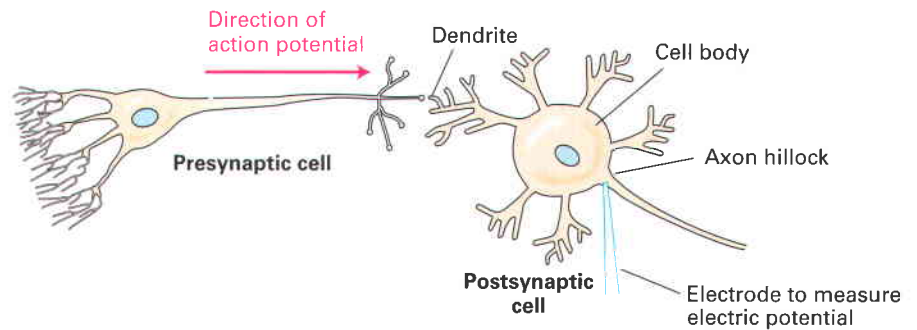

Whether a neuron generates an action potential in the axon initial segment depends on the balance of the timing, amplitude, and localization of all the various inputs it receives; this signal computation differs for each type of neuron. In a sense, each neuron is a tiny computer that averages all the receptor activations and electric disturbances on its membrane and makes a decision whether to trigger an action potential and conduct it down the axon. An action potential will always have the same *magnitude* in any particular neuron. As we have noted, the *frequency* with which action potentials are generated in a particular neuron is the important parameter in its ability to signal other cells.

Gap Junctions Also Allow Neurons to Communicate

Chemical synapses employing neurotransmitters allow one-way communication at reasonably high speed. However sometimes signals go from cell to cell electrically, without the intervention of chemical synapses. *Electrical synapses* depend on **gap junction** channels that link two or more cells (Chapter 19). The effect of gap junction connections is to perfectly coordinate the activities of joined cells. An electrical synapse also is *bidirectional*; either neuron can excite the other. In the neocortex and thalamus and some other parts of the brain, electrical synapses are common. The key feature of electrical synapses is their speed. While it takes about 0.5–5 ms for a signal to cross a chemical synapse, transmission across

► **EXPERIMENTAL FIGURE 23-23** Incoming signals must reach the threshold potential to trigger an action potential in a postsynaptic cell.

In this example, the presynaptic neuron is generating about one action potential every 4 milliseconds. Arrival of each action potential at the synapse causes a small change in the membrane potential at the axon hillock of the postsynaptic cell, in this example a depolarization of ≈ 5 mV. When multiple stimuli cause the membrane of this postsynaptic cell to become depolarized to the threshold potential, here approximately -40 mV, an action potential is induced in it.

an electrical synapse is almost instantaneous, on the order of a fraction of a millisecond. The cytoplasm is continuous between the cells. In addition, the presynaptic cell (the one sending the signal) does not have to reach a threshold at which it can cause an action potential in the postsynaptic cell. Instead, any electrical current continues into the next cell and causes depolarization in proportion to the current.

An electrical synapse may contain thousands of gap channels, each composed of two hemichannels, one in each apposed cell. Gap junction channels have a structure similar to conventional gap junctions (Chapter 19). Each hemichannel is an assembly of six copies of the connexin protein. Since there are about 20 mammalian **connexin** genes, diversity in channel structure and function can arise from the different protein components. The 1.6–2.0-nm channel itself allows the diffusion of molecules up to about 1000 Da in size and has no trouble at all accommodating ions.

KEY CONCEPTS OF SECTION 23.3

Communication at Synapses

- Synapses are the junctions between a presynaptic cell and a postsynaptic cell, and consist of small gaps.
- Neurotransmitters are released by the presynaptic cell using exocytosis. They diffuse across the synapse and bind to receptors on the postsynaptic cell, which can be a neuron or a muscle.
- Chemical synapses of this sort are unidirectional (see Figure 23-4).
- Neurotransmitters (see Figure 23-19) are stored in hundreds to thousands of synaptic vesicles in the axon termini of the presynaptic cell (see Figure 23-18). When an action potential arrives there, voltage-sensitive Ca^{2+} channels open and the calcium causes synaptic vesicles to fuse with

the plasma membrane, releasing neurotransmitter molecules into the synapse (see Figure 23-20).

- Communication between presynaptic and postsynaptic cells is abundant as a synapse is being formed. Cell-adhesion molecules keep the cells aligned. Neurons induce the accumulation of acetylcholine receptor, for example, in the postsynaptic muscle plasma membrane in the vicinity of a synapse.
- Synaptic vesicles fuse to the plasma membrane using cellular machinery that is standard issue for exocytosis, including SNAREs, syntaxin, and SNAP proteins. Synaptotagmin protein is the calcium sensor that detects the action potential–stimulated rise in calcium that leads to synaptic vesicle membrane fusion (see Figure 23-20).
- Dynamin, an endocytosis protein, is critical for the formation of new synaptic vesicles, probably to “pinch off” inbound vesicles.
- Neurotransmitter receptors fall into two classes: ligand-gated ion channels, which permit ion passage when open, and G protein–coupled receptors, which are linked to a separate ion channel.
- At synapses impulses are transmitted by neurotransmitters released from the axon terminal of the presynaptic cell and subsequently bound to specific receptors on the postsynaptic cell (see Figure 23-4).
- Low-molecular-weight neurotransmitters (e.g., acetylcholine, dopamine, epinephrine) are imported from the cytosol into synaptic vesicles by H^+ -linked antiporters. V-class proton pumps maintain the low intravesicular pH that drives neurotransmitter import against a concentration gradient.
- Arrival of an action potential at a presynaptic axon terminal opens voltage-gated Ca^{2+} channels, leading to a localized rise in the cytosolic Ca^{2+} level that triggers exocytosis of

synaptic vesicles. Following neurotransmitter release, vesicles are formed by endocytosis and recycled (see Figure 23-20).

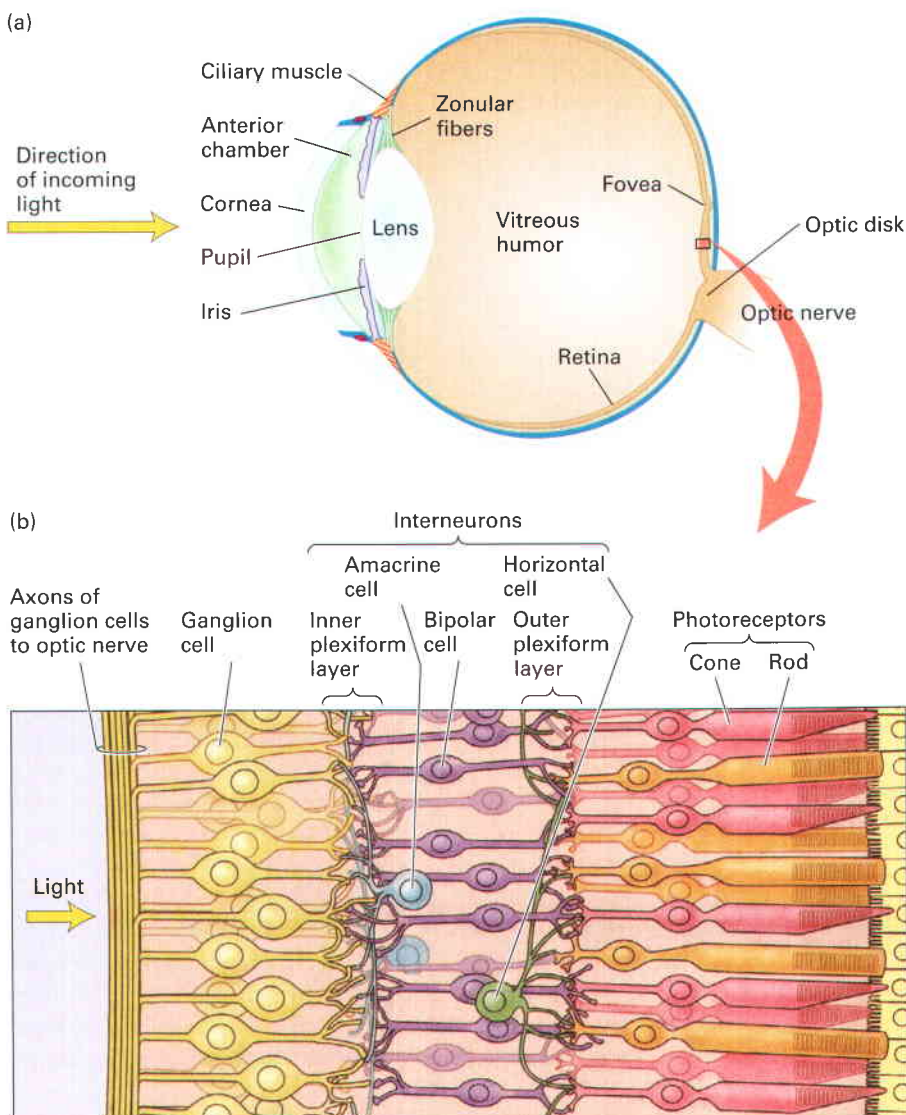

- Coordinated operation of four gated ion channels at the synapse of a motor neuron and striated muscle cell leads to release of acetylcholine from the axon terminal, depolarization of the muscle membrane, generation of an action potential, and then contraction (see Figure 23-21).
- The nicotinic acetylcholine receptor, a ligand-gated cation channel, contains five subunits, each of which has a transmembrane α helix (M2) that lines the channel (see Figure 23-22).
- A postsynaptic neuron generates an action potential only when the plasma membrane at the axon hillock is depolarized to the threshold potential by the summation of small depolarizations and hyperpolarizations caused by activation of multiple neuronal receptors (see Figure 23-23).
- Electrical synapses are direct, gap junction connections between neurons. Electrical synapses, unlike chemical synapses that employ neurotransmitter systems, are extremely fast in signal transmission and are bidirectional.

23.4 Sensational Cells: Seeing, Feeling, Hearing, Tasting, and Smelling

Dramatic progress has been made in understanding how our senses record impressions of the outside world, and how that information is processed by the brain. In this section we discuss cellular and molecular mechanisms and specialized nerve cells underlying vision, touch, hearing, taste, and olfaction.

The Eye Features Light-Sensitive Nerve Cells

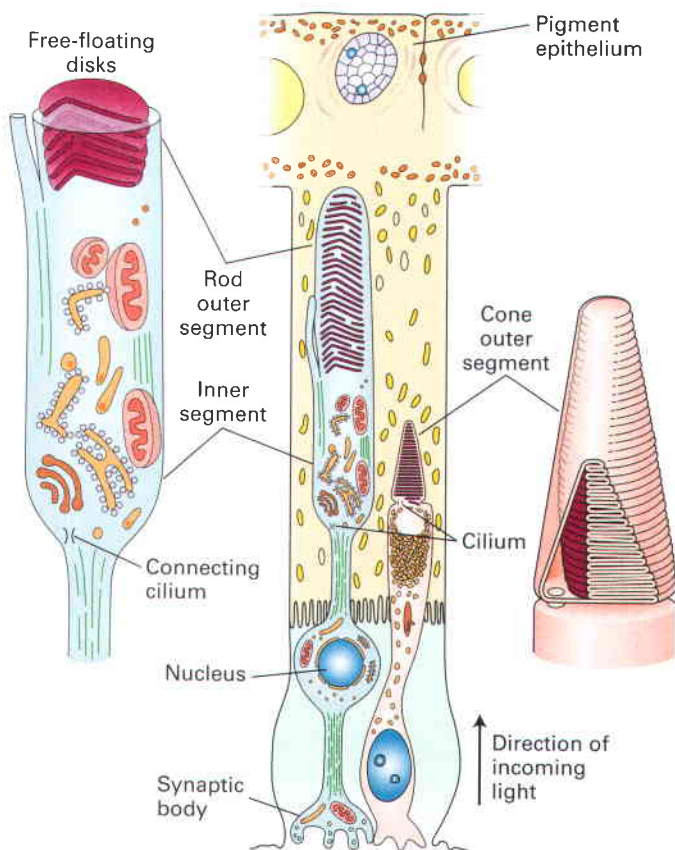

While owls would favor hearing, and dogs smell, most humans would choose vision as the sense that provides the most effective window on the world. Light is fast, about 300,000 km/s, and moves in straight lines, so it is excellent for information transfer. The human eye is a complex structure that gathers light from the environment and focuses it on specialized light-sensitive nerve cells, which send signals to the brain, where they are translated into an image (Figure 23-24a).

◀ **FIGURE 23-24 Structure of the human eye and three classes of neurons in the retina.** (a) The main tissues of the eye. Incoming light passes through the cornea, is focused by the lens, and activates light-sensing cells located in the retina. The iris restricts the amount of light entering the lens. The lens is supported by the zonular fibers, and moved by the ciliary muscle. The eye is filled with transparent, cushioning, vitreous fluid. The fovea is the location of the highest density of cells, and consequently senses the highest-resolution image. There is a blind spot (optic disc) where the optic nerve leaves the eye. (b) Detailed organization of cells in the retina. Note that incoming light has to pass through multiple layers of neurons before reaching the photoreceptor cells, the rods and cones. The interneurons include horizontal cells; bipolar cells, of which there are about a dozen types; and amacrine cells, of which there are more than 20 types. Retinal ganglion cells carry the signal information to the optic nerve. The two plexiform layers are where most connections are made. [Part (a) adapted from D. Randall, W. Burggren, and K. French, 2002, *Eckert Animal Physiology*, 5th ed., W. H. Freeman and Company, p. 259; part (b) from B. Kolb and I. Q. Whishaw, 2006, *An Introduction to Brain and Behavior*, 2d ed., Worth, p. 278.]

The human retina (Figure 23-24b) is about 200 μm thick. As we learned in Chapter 15, it contains two types of photoreceptors, *rods* and *cones*, which are the primary recipients of visual stimulation. Cones are involved in color vision, while rods are stimulated by weak light, like moonlight, over a range of wavelengths. In contrast to many other sensory neurons, stimulated photoreceptor cells become *hyperpolarized*, not depolarized. The photoreceptors synapse on layer upon layer of interneurons that are innervated by different combinations of photoreceptor cells. All these signals are processed and interpreted by the part of the brain called the *visual cortex*. In each eye we have about 6 million cones and 120 million rods, connecting to 540 million visual cortex cells, so a substantial part of our nervous system is devoted to detecting and interpreting light.

Rods detect faint light, as low as a single photon, owing to their sensitive visual pigment and their ability to amplify a

▲ **FIGURE 23-25 Rods and Cones.** Vertebrates have two types of photoreceptors, rods and cones, that differ morphologically and functionally. Cones detect color; rods detect light intensity but not color and are more sensitive than cones to low light levels. The pigments that absorb light are packed into flattened disks in the outer segments of rods and cones. Note that the outer segments containing the pigments are located on the innermost side of the retina, so light must traverse layers of cells before reaching the sensory organelles. [Adapted from D. Randall, W. Burggren, and K. French, 2002, *Eckert Animal Physiology*, 5th ed., W. H. Freeman and Company, p. 261.]

weak signal. Rods have a single pigment that allows an equal response to a broad spectrum of wavelengths. Cones (Figure 23-25) come in the three types: red, green, and blue. The brain deduces color information by comparing the signals from a trio of cone cells, one of each kind, that share the same *receptive field*. The receptive field of each cell is measured as an angle with its vertex at the cell. If cells are densely packed and each has a small receptive field, highly detailed visual information is collected. If cells are less dense, have large receptive fields, or both, the image will have lower resolution.

Rods and cones are packed with light-absorbing pigments consisting of an *opsin* protein covalently bound to a small light-sensitive molecule called *11-cis-retinal*. These pigments are arranged in flattened membrane disks in the outer segments of rods and cones (Figure 23-25; also see Figure 15-16). Opsin-containing disks are continuously replaced, completely turning over about every 12 days. Opsins are G protein-coupled receptors that are activated when their bound retinal absorbs light. The pigment in rods is called *rhodopsin*. Light-induced isomerization of the retinal portion of rhodopsin alters the protein's conformation, triggering a signaling pathway that closes Na^+ and Ca^{2+} channels in the rod-cell membrane (see Figure 15-18). The pigments in cones contain different opsins, but they function similarly to rhodopsin.

Visual acuity depends on how finely the incoming light can be reproduced as action potential signals in the map of the retina and further along in the circuitry. The density and numbers of rods would suggest a higher-resolution image than we actually see. In fact their signals converge onto a smaller number of bipolar cells, so some resolution is lost. In contrast the cone cells have very high spatial resolution. Most of the retina has a high density of rod cells and sparse cone cells. The exception is a central region called the *fovea* (see Figure 23-24a), which is mostly made up of cone cells, about 150 cells across its 300- μm diameter. In the fovea the cone cells have small receptive fields, on the order of 0.01 degree, which allows high-resolution representation of incoming light patterns. The receptive fields of rod cells are generally larger, up to several degrees, lowering the sharpness of the image. In dim light our sight is blurry because we depend on rods rather than cones.

Eyes Reflect Evolutionary History

The eye structures of organisms reflect their different evolutionary histories. The eyes of some simpler animals, such as planarians, consist of a light-sensitive optic nerve accompanied by pigment cells, without lenses or other means to obtain a sharp image. In contrast, the compound eyes of insects have hundreds of lenses, one for each facet of the eye (see Figure 16-21). Yet, some of the proteins that regulate eye development play the same role in a vast array of animals that have strikingly different eyes. One of the most peculiar aspects of the human retina, caused by the way our eyes evolved from more primitive light-sensing structures, is that the photosensitive cells lie *behind* the mass of neural connections. Light must pass through the lens, vitreous fluid, and axons and dendrites

and interneurons before reaching the photoreceptors (see Figure 23-24b; note direction of incoming light). Compared with optimal design of a light detector, the eye is backwards. The arrangement is also the reason we have a blind spot. Where the optic nerve connects, no light can be sensed.

Integrated Information from Multiple Ganglion Cells Forms Images of the World

If each photoreceptor cell responds to a tiny point of light, how is a larger image of the world assembled? The mass of neurons in the visual system makes this problem seem insurmountable. Fortunately the cells are organized in a rather simple hierarchical fashion that has allowed considerable progress to be made. The first stage of information processing is done in the retina, immediately after light is received by interneurons (see Figure 23-24b). In fact, processing of visual information begins at the very first synapses where the photoreceptor cell connects to interneurons. Interneurons allow signals from multiple photoreceptor cells to be combined and compared. By the time signals leave the eye via the axons of retinal ganglion cells that constitute the optic nerve, each signal conveys not a point of light but a *pattern* of light. Let us start by looking at what sorts of pattern information emerges from the retina.

The experimental approach to the problem uses electrical recordings done with electrodes inserted into individual ganglion cells. At the same time the eye of an anaesthetized animal is exposed to small spots of light shining on the retina. The first step is to identify the part of the retina that stimulates the particular cell into which the electrode is inserted. Next, variations in the size, position, and shape of the light spot are tested.

Remarkably, **bipolar cells** (Figure 23-24b, shown in purple) and the retinal ganglion cells to which they connect (Figure 23-24b, shown in yellow) are sensitive to particular patterns of retinal illumination. This is possible because each photoreceptor (rod or cone) cell simultaneously receives light *and*, a signal from nearby photoreceptor cells. These lateral signals are carried by *horizontal cells*, a type of interneuron (Figure 23-24b, shown in green). In essence, each photoreceptor cell compares what it sees to what it learns its neighbors are seeing.

Let's look at the consequences of such an arrangement. The receptive field of a single bipolar cell is approximately circular, and its information is passed on to a retinal ganglion cell that therefore has the same field. A single bipolar cell receives inputs from a group of photoreceptor cells covering the area of a circle. Each bipolar cell receives signals from a different circle of cells. This type of receptive field pattern is called *center-surround* (Figure 23-26). There is a critical added feature: a bipolar cell responds to light shining in the center of its receptive field—the group of photoreceptor cells near the center of the circle—by producing a set of action potentials. However, action potentials are *inhibited* if light strikes photoreceptor cells surrounding the central part of the circle (Figure 23-26a). This type of cell is an *on-center* cell because light directed at the middle of the field turns the cell on. Some bipolar cells, and therefore their corresponding retinal ganglion cells, have just

Podcast: Vision—Detecting and Recognizing Patterns

▲ **FIGURE 23-26 Center-surround receptive fields of retinal neurons.** Each retinal ganglion cell responds to a roughly circular receptive field that corresponds to a specific part of the retina. By exposing eyes to different illumination patterns and simultaneously recording individual retinal ganglion neurons, researchers discovered that each neuron responds to an annulus (doughnut)-shaped field, a pattern described as *center-surround*. Some cells fire trains of action potentials when the center is dark and the periphery is light (“off-center field”); some respond to the opposite pattern (“on-center field”). (a) An on-center field. *Spot on center*: a light spot focused on the center of the cell’s field triggers a series, or “train,” of action potentials. *Spot on surround*: a light spot focused on the peripheral region of the same cell’s field inhibits action potentials. *Center illuminated*: illumination of the entire center spot of the field triggers a rapid burst of action potentials. *Surround illuminated*: illumination of the entire surround region has a strong damping effect on action potentials. *Diffuse illumination*: diffuse illumination of the cell’s entire receptive field causes a weak response, i.e., a damping of the response seen if only the center is illuminated. (b) An “off-center” field of a cell that has the opposite property of the cell in (a). Illumination of a spot in the center of the off-center cell’s field inhibits action potentials, while a spot of light in the periphery stimulates action potentials. [Adapted from F. Delcomyn, 1998, *Foundations of Neurobiology*, W. H. Freeman and Company, p. 265.]

the opposite response: light in the center reduces the frequency of action potentials, while light in the surround stimulates more frequent action potentials (Figure 23-26b). This is an *off-center* cell. The two types of cells, on-center and off-center, are present in roughly equal numbers. Both types of cells sense the relative light intensity in the center versus the surround, not the absolute amount of light in either place. *Bipolar and retinal ganglion cells are therefore contrast detectors.*

How do bipolar cells integrate photoreceptor cell information to detect center-surround patterns? To answer this

we will look at the connections of cone photoreceptor cells to bipolar and horizontal interneurons (see Figure 23-24b). On-center and off-center bipolar cells differ in the types of channel proteins they use, giving opposite responses to the same glutamate neurotransmitter. For simplicity, here we will focus on bipolar on-center cells.

Bipolar and horizontal interneuron cells, like photoreceptor cells, lack voltage-gated Na^+ channels, so none of them generate action potentials. Instead, the secretion of neurotransmitters from the cells' synaptic termini is controlled by the

► **FIGURE 23-27 The influence of light and dark on on-center cone cells in image interpretation.**

(a) In the dark, a cone cell in the center of the receptive field is depolarized, resulting in the release of glutamate. Glutamate inhibits the bipolar cell, causing it to hyperpolarize and thus preventing all but rare action potentials. Note that bipolar off-center cells have the opposite response to glutamate. (b) When light strikes the cone cell, it becomes hyperpolarized, with a resultant drop in glutamate secretion. Free of the inhibitory effect of glutamate, the bipolar cell depolarizes, and frequent action potentials result. (c) The activity of a cone cell is affected by surrounding cone cells through horizontal cells that connect cells laterally. If only the center cell is illuminated, the cell will stimulate the bipolar and consequently the ganglion cells. If both center *and* surround cells are illuminated, the center cell's signal to the bipolar cell will be inhibited. The system is therefore a contrast detector, looking for light patterns that illuminate a small center spot but not the surrounding retina. Here are the steps involved: Light striking the cone cell in the surround of a receptive field hyperpolarizes it **1**, which results in a reduction in the release of glutamate **2**. This, in turn, results in hyperpolarization of the horizontal cell, causing it to release less inhibitory transmitter to the center cone cell **3**. The center cone cell, in the absence of inhibition from surround cells, is depolarized **4**, desensitizing it to light and inducing an increase of glutamate release to the on-center bipolar cell, as in (a). The bipolar cell is therefore hyperpolarized **5**, resulting in suppression of action potentials **6**. The schemata shown are highly simplified, since all the cells can be connected to more than one cell at each stage of signal transmission.

degree of membrane polarization. In the dark, cone cells have a membrane potential of about -40 mV, which opens voltage-gated Ca^{2+} channels and causes the continuous release of the neurotransmitter glutamate (Figure 23-27a). This glutamate, coming from cone cells in the center of a receptive field, hyperpolarizes the bipolar neuron that covers that field, suppressing action potentials. Light striking the center field cone cells hyperpolarizes them to about -65 mV by suppressing an inward flow of Na^+ and other ions, closing the Ca^{2+} channels and reducing emission of glutamate (Figure 23-27b). This depolarizes the bipolar neuron, which in turn depolarizes ganglion cells and triggers action potentials to be sent to the brain.

On-center bipolar cells are most stimulated if the cone cells in the center of the receptive field are illuminated and the surround cone cells are in the dark. How do bipolar cells detect the light condition in the surround part of the receptive field? The surround input is mediated by horizontal cell interneurons (see Figure 23-24b, green cells). If there is light on a cone cell in the surround region of the field, the horizontal cell that is connected to that cone cell becomes hyperpolarized which means it reduces inhibitory transmitter release onto the cone cell in the center of the receptive field. The central cone cell becomes depolarized, as though it was in the dark, and consequently the bipolar cell in the center of the receptor field is hyperpolarized (see Figure 23-27c). Ganglion cell action potentials in the center of the field are suppressed despite the light falling on the central cone cells. Thus light in the surround inhibits sensing of the light in the center, a contrast detector.

The retina's processing of visual information is just the beginning of a hierarchical chain of pattern representation and interpretation events. The refined processing of visual information occurs, it must be remembered, by reading trains of action potentials coming from the eye. In the visual cortex, cells are found that are specifically sensitive to bars of light and dark, and each cell prefers bars at a certain angle. It is easy to see how the information that passes through retinal ganglion cells, the center-surround information, can be used to detect a bar of light or dark. If a visual cortex cell is stimulated by ganglion cells whose visual fields are arranged in a line, the integrated pattern would be a bar that passes through the centers of the individual ganglion cells' center-surround patterns (Figure 23-28). Further combinations can lead to recognition of more complex patterns by single cells. Some cells respond to a change of light—on to off or off to on. Others respond to edges, moving spots, or moving bars. Some cells in the higher levels of the visual cortex have even been found to recognize a certain face.

The discovery of cells that integrate spatial information from cells that have simple receptive fields was described by Nobel prizewinner David Hubel, who made the discovery with his collaborator Torsten Wiesel:

Our first real discovery came about as a surprise. For three or four hours, we got absolutely nowhere. Then gradually we began to elicit some vague and inconsistent responses by stimulating somewhere in the midperiphery of the retina. We were inserting the glass slide with its black spot into the slot of the ophthalmoscope when suddenly, over the audio monitor, the cell went off like a machine gun.

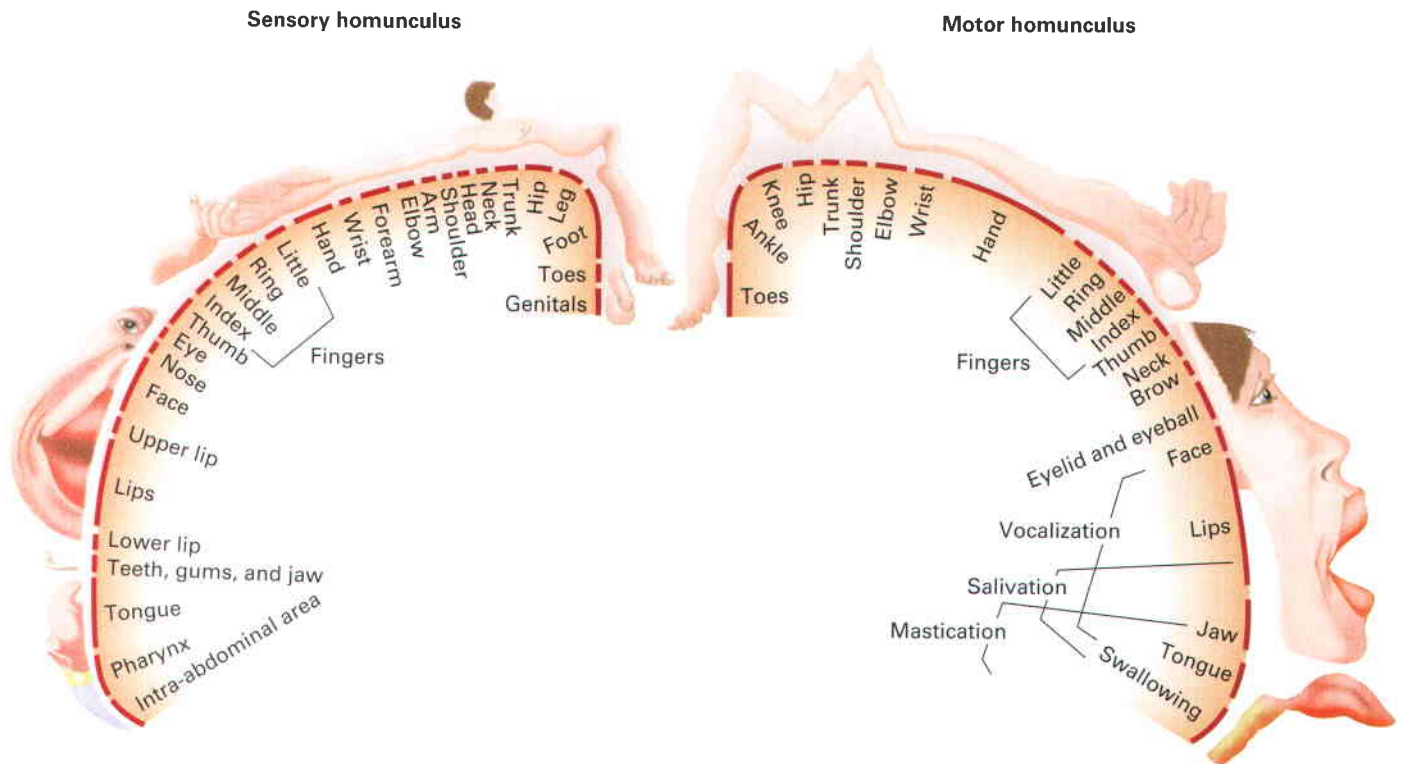

▲ **FIGURE 23-28 Complex pattern recognition.** A cortical cell responds to the sum of multiple ganglion cell "centers," thus detecting the vertical bar shown. Other cortical cells respond to different combinations of ganglion receptor fields or combinations of cortical neuron fields to recognize more complex patterns.

After some fussing and fiddling, we found out what was happening. The response had nothing to do with the black dot. As the glass slide was inserted, its edge was casting onto the retina a faint but sharp shadow, a straight dark line on a light background. That was what the cell wanted, and it wanted, moreover, in just one narrow range of orientations. This was unheard of. It is hard now to think back and realize just how free we were from any idea of what cortical cells might be doing in an animal's daily life.

Mechanosensory Cells Detect Pain, Heat, Cold, Touch, and Pressure

Our skin, especially the skin of our fingers, is expert at collecting sensory information. Our whole body, in fact, has numerous **mechanosensors** embedded in its various tissues. These sensors frequently make us aware of touch, the positions and movements of our limbs or head (proprioception), pain, and temperature, though we often go through periods where we ignore the inputs. Mammals use one set of receptor cells to report on touch, and other sets of receptors for temperature, heat, and pain. Pain receptors, called **nociceptors**, respond to mechanical change, heat, and certain toxic chemicals (e.g., hot pepper). Genetic insensitivity to pain is

▲ **FIGURE 23-29 Homunculus.** The homunculus is a map of the regions of the brain's cortex that are dedicated to particular functions. Sensory and motor homunculi are shown. The face and

hands take up large portions of the brain's sensory and motor capacities. [Adapted from D. Randall, W. Burggren, and K. French, 2002, *Eckert Animal Physiology*, 5th ed., W. H. Freeman and Company, p. 292.]

often due to mutations in a gene, *trkA*, that encodes a receptor for nerve growth factor (NGF), a protein mostly studied in different contexts. NGF and other neurotrophins have now been implicated as signals of pain. Thermal receptors detect temperature changes. These cells steadily send action potentials (2–5/s) that indicate the current temperature. Each temperature range has receptors tuned to it, so *which* cells are firing conveys the temperature.

Connecting from the skin's sensory cells to the brain does not take many synapses. Mechanosensors in the skin, for example, connect to the medulla, where they pass the signal along to neurons that go to the thalamus. A third neuron goes from there to the sensory cortex. A mere trio of neurons connects the periphery to the brain centers. In the cortex the sensory inputs are combined, through interneurons, with proprioceptive inputs that report the positions of muscles and joints. Presumably this makes it possible to know *what* you are feeling and *where* it must be if *that* arm in *that* position is feeling it. Proprioception receptors take multiple forms. Some of the most studied are muscle spindles, sensory assemblages that are buried in muscles to report on how much that muscle is extended. Such stretch receptors are crucial to smooth movement and well-timed responses.

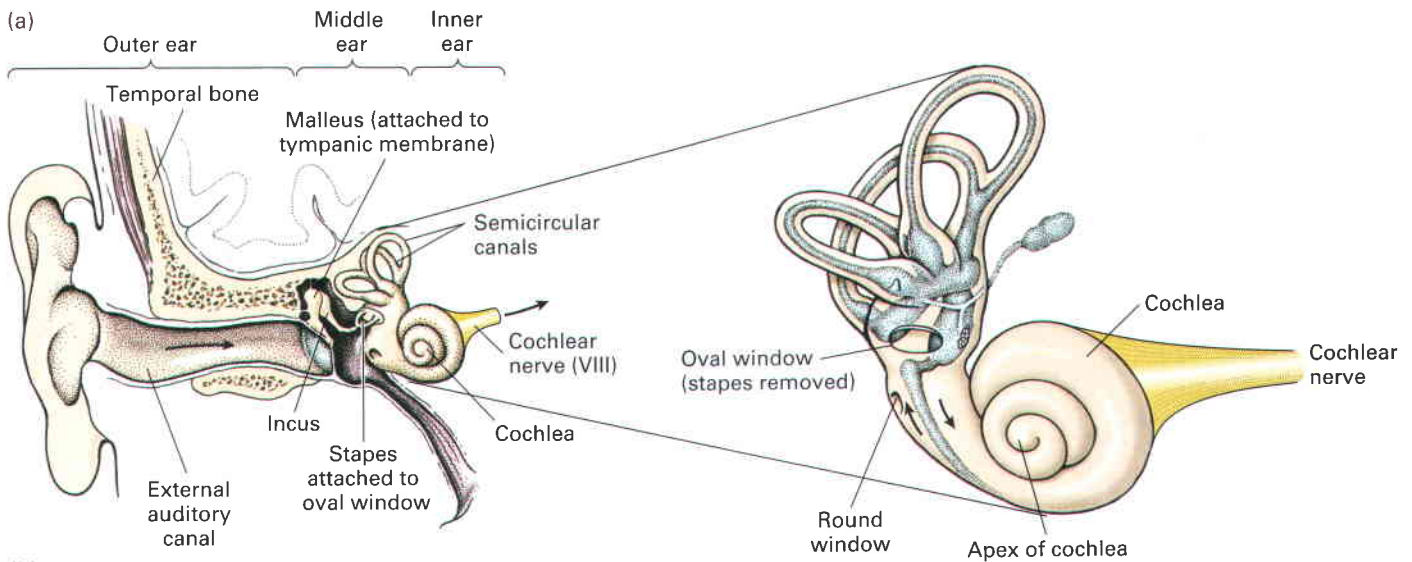

Remarkably, the organization of the body is reflected in a map, or more accurately several maps, in the brain. The organization of the cortical neurons that respond to sensory signals is physically related to the spatial origins of the signals. In the brain the sensory neurons are laid out in a distorted map of the body. The motor neurons are also

arranged in a map that can be aligned with the muscles they control. The maps are called the *sensory homunculus* and the *motor homunculus* (Figure 23-29). A *homunculus* is a “little human,” an image of us. The map dimensions are not proportional to the body's dimensions, because the homunculi reflect the number of sensory or motor cells rather than the area of the body. The hands and feet are highly represented and take up much more space in the sensory map.

Inner Ear Cells Detect Sound and Motion

The outer ear captures sound, which moves three tiny bones (*ossicles*) in the middle ear, which in turn transmit sound-induced motions to the inner ear, or *cochlea* (Figure 23-30a). The cochlea is shaped like a snail, with nearly three turns, and indeed the name derives from the Greek word for “snail” (*cochlos*). The cochlea houses the **organ of Corti**, the sensory part of the inner ear, which transduces mechanical movement into electrical impulses. The human organ has about 16,000 hair cells arranged in four rows (Figure 23-30b, c), attached to about 30,000 afferent neurons that carry any signals to the brain. Hair cells produce **stereocilia**, which are moved by vibrations induced by sound. The oscillating vibrations alternately bend the stereocilia one way or the other, triggering depolarization events called receptor potentials in the 10 or so axons associated with each hair cell. These receptor potentials, which are milder than full action potentials, range up to 25 mV.

Hair cells and the neurons they influence are responsive to different sound frequencies. There is a gradient across the

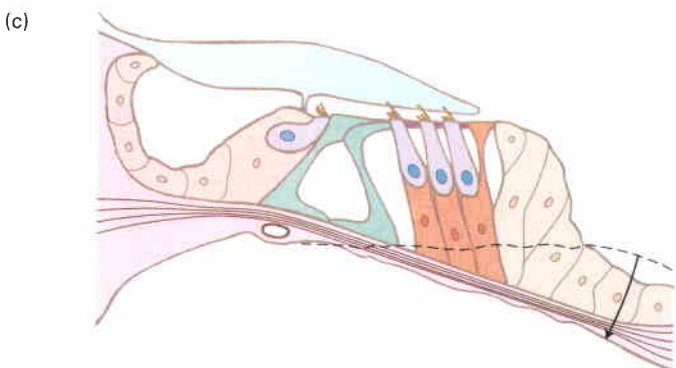

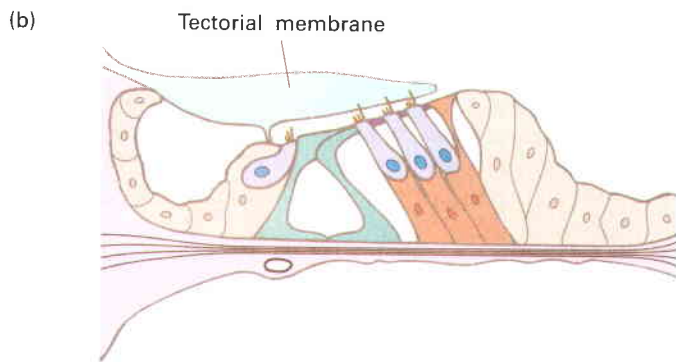

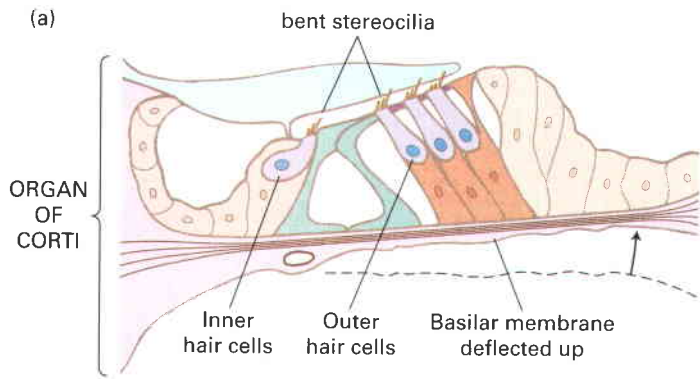

▲ FIGURE 23-30 Structures of the ear. (a) Sound enters the outer ear and travels to the middle ear, where three tiny bones (the malleus, incus, and stapes) transfer sound-induced vibration in the tympanic membrane across the middle ear to the cochlea in the inner ear, where mechanical vibration is transduced to electrical signals. The cochlea, unwound, would be 33 mm long. (b) The inner surface of the organ of Corti, found in the cochlea, as viewed by scanning electron microscopy. The tops of all the stereocilia (white) would be in contact with the tectorial membrane in the intact ear (see Figure 23-31). The stereocilia of the inner hair cells (*left row*) are arranged in a line, while the three rows of outer hair cells have stereocilia in V shapes. (c) Higher magnification of the stereocilia of outer hair cells. The hair cells are smooth except for the cilia, while surrounding support cells are covered by microvilli. [Part (a) adapted from D. Randall, W. Burggren, K. and French, 2002, *Eckert Animal Physiology*, 5th ed., W. H. Freeman and Company, p. 243. Parts (b) and (c): Courtesy of Bechara Kachar/National Institute of Health.]

cochlea of frequency sensitivity, so that the spatial locations of the cells that are stimulated reflect the frequency composition of a sound. Hair cells and neurons at one end of the cochlea hear low-frequency sounds and at the other end high frequencies. This is not because of a difference in either hairs or neurons. The graded sensitivity is due to a tapering tissue called the *basilar membrane* (Figure 23-31) that responds to low frequencies at one end and high frequencies at the other. Each frequency excites motion in a particular region of the 33-mm-long basilar membrane, which is then locally transferred to nearby hair cells. The orientation of the hair cells, and in particular of their bundles of stereocilia, with respect to the basilar membrane allows sensitive detection of deflections caused by sound. The polarity of the hair cells and their cytoskeletons are key to proper transduction of sound into electrical signals.

Some of the proteins that control the structure of hair cells and stereocilia have been identified through human genetics, tracking genes responsible for deafness. Five genes have been implicated in Usher type 1 syndrome, the

▲ FIGURE 23-31 Sterocilia movement. The stereocilia of the inner and outer hair cells (purple) are stimulated by a sideways movement with respect to the overhanging tectorial membrane, which in turn is influenced by oscillating fluid pressure changes in the organ of Corti. The fluid pressure in the organ oscillates at the frequency of the incoming sound. (a) As vibration begins, the basilar membrane (pink) is forced upward (indicated by the arrow) by fluid pressure changes, which translates into a leftward movement with respect to the tectorial membrane, thus bending the stereocilia to the right. (b) At the midpoint of the oscillation, the stereocilia relax. (c) When the oscillation goes the other way and the basilar membrane moves down (indicated by the arrow), the hair bundles are moved in the opposite direction by the shearing effect of the tectorial membrane. The motions are repeated with each wave. [Adapted from D. Randall, W. Burggren, and K. French, 2002, *Eckert Animal Physiology*, 5th ed., W. H. Freeman and Company, p. 248.]

most frequent cause of hereditary deafness and blindness in humans. The genes encode myosin VIIa, cadherin 23, protocadherin 15, a PDZ domain protein called *harmonin*, and a putative scaffolding protein called *Sans*. All these proteins are localized within stereocilia in auditory hair bundles. Harmonin associates with both F-actin and with the cadherins implicated in the disease, while myosin VIIa and *Sans* help to localize harmonin in stereocilia. These discoveries have emerged from medical genetic screening of patients and are revealing the key molecular underpinnings of stereocilia and auditory sensing.

Five Primary Tastes Are Sensed by Subsets of Cells in Each Taste Bud

Taste buds are located in bumps called *papillae*, and each bud has a pore through which fluid carries solutes inside. About 50–100 taste cells are located in each taste bud (Figure 23-32a, b). Cells in the tongue and other parts of the mouth are subjected to a lot of wear and tear, and taste bud cells are continuously replaced by cell divisions in the underlying epithelium. (A taste bud cell in rats has a lifetime of 10 days.)

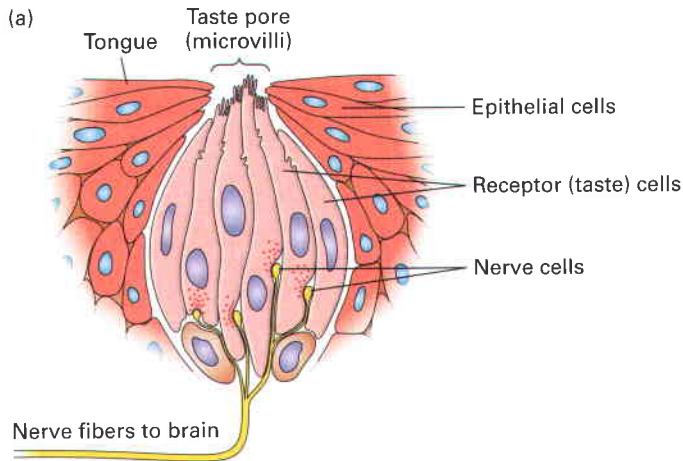

Taste cells are epithelial cells that show some of the functions of neurons. Reception of a taste signal causes cell depolarization and receptor potentials that trigger action potentials; these, in turn cause Ca^{2+} uptake through voltage-dependent Ca^{2+} channels and release of neurotransmitters at synapses. Taste cells do not grow axons, instead signaling over short distances to other neurons. In contrast to most other sensory systems, there is, as yet, no known topographic representation at any level of the brain that corresponds to the different tastes.

We taste certain chemicals, all hydrophilic, nonvolatile molecules floating in saliva. Although all tastes are sensed on all areas of the tongue and there is no topographical taste map of the tongue, selective cells do respond preferentially to certain tastes. Taste is less demanding of the nervous system than olfaction because fewer types of molecules are monitored. What is impressive is the sensitivity of taste; bitter molecules can be detected at concentrations as low as 10^{-12} M. There are receptors for salt, sweet, sour, umami (e.g., monosodium glutamate and other amino acids), and bitter (Figure 23-32c, d, e, f) in all parts of the tongue. The receptors are of two different “flavors”: channel proteins for salt and sour tastes and seven-transmembrane-domain proteins (G protein-coupled receptors) for sweetness, umami, and bitterness.

Salt is probably sensed by members of a family of Na^+ channels called *ENaC channels*, though definitive proof is lacking; other members of the family have diverse functions including neural memory. The influx of Na^+ through a channel depolarizes the cell. The role of ENaC channels as salt sensors is old, since ENaC proteins clearly detect salt in insects. In *Drosophila*, taste sensors are located in multiple places including the legs, so when the fly steps on something tasty, the proboscis extends to explore it further. However, the ENaC studies were done using fly larvae, which can respond

▼ **FIGURE 23-32 A mammalian taste bud and its receptors.**

(a) The pink cells are the taste cells. These epithelial receptor cells contact the nerve cells (yellow). The chemical signals arrive at the microvilli seen at the top. (b) Photograph of a pair of taste buds, showing the receptor cells. The microvilli are clearly visible in the taste bud on the left. (c–f) Types of taste receptors. [Part (a) adapted from B. Kolb and I. Q. Whishaw, 2006, *An Introduction to Brain and Behavior*, 2d ed., Worth, p. 400; Part (b) from Ed Reschke/Peter Arnold.]

Sugars

to salt if they have either of their two ENaC proteins. Sour reception is the detection of H^+ ions, which can move through the same channels as Na^+ . H^+ may also be sensed due to its interference with K^+ channels and consequent increase in intracellular positive charge (i.e., a depolarizing effect).

Bitter tastes are more diverse than salt and have been found to depend on a diverse family of about 25 genes encoding various T2Rs, taste-receptor proteins with seven transmembrane α -helical domains; they are members of the class of proteins known as G protein-coupled receptors (GPCRs). These GPCRs depolarize the cell by triggering, through G proteins, the activity of phospholipase C (PLC), which increases the concentration of IP_3 (see Figure 15-30). This causes Ca^{2+} release from intracellular compartments and consequent depolarization. One G protein involved in bitter taste transduction is called *gustducin*.

The first member of the T2R family to be identified came from human genetics studies that showed an important bitterness-detection gene on chromosome 5. Multiple T2R types can be expressed in the same taste cell, and about 15 percent of all taste cells express T2Rs. Bitter taste molecules are quite distinct in structure, which probably accounts for the need for the diverse family of T2Rs. Mice that have five amino acid changes in the receptor T2R5 are unable to taste the bitter taste of cycloheximide (a protein synthesis inhibitor, Chapter 8).

A dramatic gene regulation swap experiment was done to demonstrate the role of T2R proteins. Mice were engineered to express a bitter taste receptor, a T2R protein, in cells that normally detect sweet tastes that attract mice. The mice developed a strong attraction for bitter tastes, evidently because the cells continued to send a “go and eat this” signal even though they were detecting bitter taste. This experiment demonstrates that the specificity of taste cells is determined within the cells themselves, and that the signals they send are interpreted according to the neural connections made by that class of cells. This in turn implies a highly regulated system connecting the different classes of taste receptor cells to specific higher regions of the brain.

One bitter taste is especially famous because it is often used in genetics classes to teach about human variation. The chemical phenylthiocarbamide (PTC) tastes exceedingly bitter to many people but is tasteless to others. Human sensitivity to PTC can differ by a factor of 16. The inability to detect PTC is inherited as a recessive trait, meaning that tasting is dominant over nontasting.

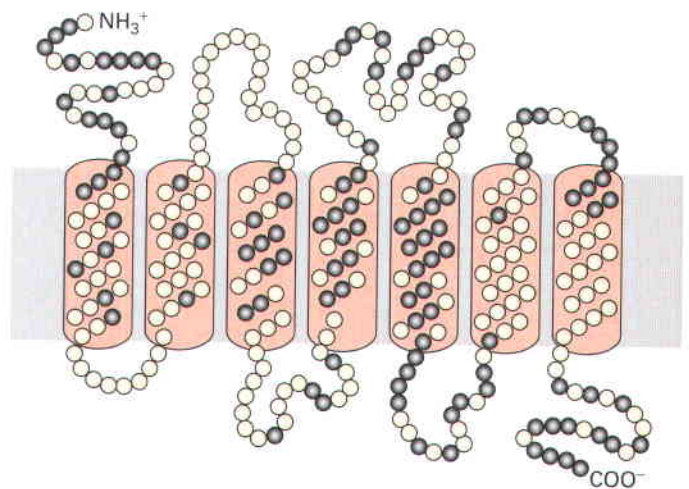

Sweet and umami tastes are detected by a protein family related to the T2Rs, called T1Rs. When T1R proteins bind an appropriate *tastant*, they act through G proteins to trigger the release of calcium inside the cell. The three mammalian T1Rs differ from one another in a small number of amino acids. A T1R protein looks like a GPCR, but has an additional large extracellular domain that is the taste-binding part of the protein. This domain, in the taste-sensing glutamate receptor, closes around glutamate in a way that is described by analogy to a Venus fly trap. T1Rs form dimers and heterodimers, and the code of responses to different molecules is still under investigation. Mice lacking T1R2 or

T1R3 fail to detect sugar; it is thought that the actual receptor is a heterodimer of the two. T1R3 appears to be a receptor for both sweet tastes and umami, and that is because it detects sweets when combined with T1R2 and umami when it combines with T1R1. Accordingly, taste cells express T1R1 or T1R2 but not both, as otherwise they would send an ambiguous message to the brain.

A Plethora of Receptors Detect Odors

The perception of volatile airborne chemicals imposes different demands than the perception of light, sound, touch, or taste. Light is sensed by only four molecules, tuned to different wavelengths. Sound is detected by mechanical effects through hairs that are tuned to different wavelengths. Touch requires a small number of types of transducers. The sense of taste measures a small number of substances dissolved in water. In contrast to all these other senses, olfactory systems can discriminate between many hundreds of volatile molecules moving through air. Discrimination between a large number of chemicals is useful in finding food or a mate, sensing pheromones, and avoiding predators, toxins, and fires. *Olfactory receptors* can work with enormous sensitivity. Male moths, for example, can detect single molecules of the signals sent drifting through the air by females.

In order to cope with so many signals, the olfactory system employs a large family of olfactory receptor proteins. Humans have about a thousand olfactory receptor genes, of which about a third are functional (the rest are unproductive pseudogenes), a remarkably large proportion of the estimated 25,000 human genes. Mice are more efficient, with 1300 genes, of which about 1000 are functional. That means 3 percent of the mouse genome is composed of olfactory receptor genes. *Drosophila* has about 60 olfactory receptor genes. In this section we will examine how olfactory receptor genes are

▲ **FIGURE 23-33 Sequence organization in olfactory receptors.** Olfactory receptors are seven-transmembrane-domain G protein-coupled receptor proteins. The cylinders indicate the extent of alpha helices that cross the membrane. Residues in black are highly variable, and some of these differences account for specific interactions with odorants. [From L. Buck and R. Axel, 1991, *Cell* 65:175.]

employed, and how the brain can recognize which odor has been sensed—the initial stages of interpretation of our chemical world. Odor molecules are called *odorants*. They have diverse chemical structures, so olfactory receptors face some of the same challenges faced by antibodies—the need to bind and distinguish many variants of relatively small molecules.

Olfactory receptors are seven-transmembrane-domain proteins (Figure 23-33). In mammals, olfactory receptors are produced by cells of the nasal epithelium. These cells, called *olfactory receptor neurons (ORNs)*, transduce the chemical signal into action potentials (Figure 23-34). In *Drosophila*, ORNs are located in the antennae. The ORNs project their axons to the next higher level of the nervous system, which in mammals is located in the olfactory bulb of the brain. The ORN axons synapse with dendrites from *projection neurons* in insects (called *mitral neurons* in mammals); these synapses occur in the clusters of synaptic structures called *glomeruli*. The projection neurons connect to higher olfactory centers in the brain (Figure 23-35).

Each ORN produces only a single type of odorant receptor. Any electrical signal from that cell will convey to the brain a simple message: “my odor is binding to my receptors.” Receptors are not always completely monospecific for odorants. Some receptors can bind more than one kind of molecule, but the molecules detected usually are closely related in structure. Conversely, some odorants bind to multiple receptors.

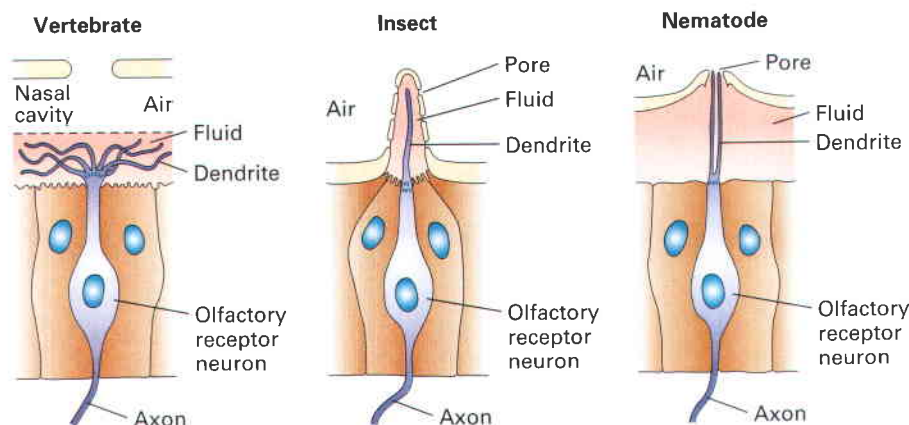

There are about a million ORNs in the mouse; so on average each of the thousand or so olfactory receptor genes is active in a thousand cells. There are about 2000 glomeruli (2 for each gene), so on average the axons from 500 ORNs converge on each glomerulus. From there the axons of about 50,000 mitral neurons, about 25 per glomerulus, connect to higher brain centers. Note that in contrast to the visual system, very little signal interpretation and refinement occurs in the sensory epithelium or even the projection neurons. The initial sensory information is carried to higher parts of the brain without processing, a simple report of what has been detected with no further analysis or commentary.

The one neuron–one receptor rule extends to *Drosophila*. Detailed studies have been done in larvae, where a simple olfactory system with only 21 ORNs uses about 10–20 olfactory receptor genes. It appears that a unique receptor is expressed in one ORN, which sends its projections to one glomerulus.

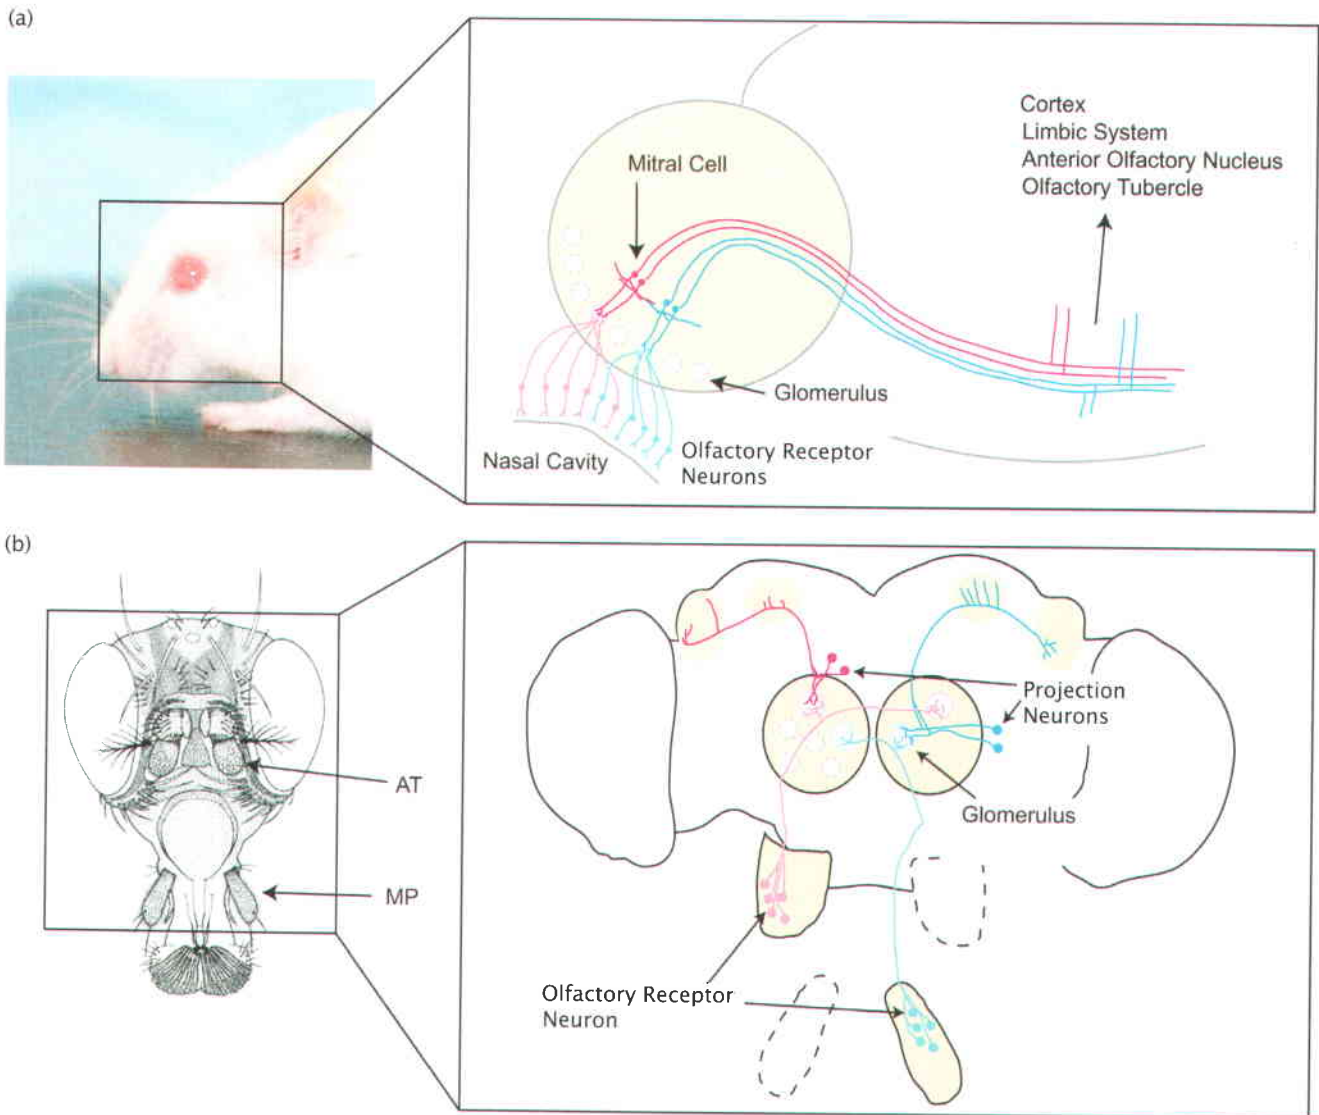

ORNs can send either excitatory or inhibitory signals from their axon termini, probably in order to distinguish attractive versus repulsive odors. The ORNs project to glomeruli in the antennal lobe of the larval brain. The research began with tests of which odorants bind to which receptors (Figure 23-36a). Some odorants are detected by a single receptor, some by several, so the combinatorial pattern allows many odorants to be distinguished. The small total number of neurons has allowed a map to be constructed showing which odorants are detected by every glomerulus (Figure 23-36b). One striking finding was that glomeruli located near each other respond to odorants with related chemical structures, e.g., linear aliphatic compounds or aromatic compounds. The arrangement may reflect evolution of new receptors concomitant with a process of subdivision of the olfactory part of the brain.

The simple system of having each cell make only one receptor type also has some impressive difficulties: (1) Each receptor must be able to distinguish a type of odorant molecule or a set of molecules with specificity adequate to the needs of the organism. A receptor stimulated too frequently will probably not be too useful. (2) Each cell must produce one and only one receptor. All the other genes must be turned off. At the same time the collective efforts of all the cells in the nasal epithelium must allow the production of enough different receptors to give the animal adequate sensory versatility. It does little good to have hundreds of receptors if most of them are never used, but it is a regulatory challenge to turn on one and only one gene in each cell and yet use all the genes in the complete population of cells. (3) The wiring of the olfactory system must make discrimination among odorants possible. This could involve either a relatively random wiring that is then interpreted based on experience, or a programmed wiring that is reproducible from individual to individual. The brain must learn which cell is receiving which odorant so that electrical signals from the nose can be interpreted. It is often the case that a response to a particular odor is programmed in the genes, like a behavioral response to a pheromone. In such cases the brain must know which cells are detecting that pheromone. Otherwise the animal might be feeling romantic when it should be running away as fast as possible.

The solution to the first problem is the great variability of the olfactory receptor proteins, both within and between

◀ **FIGURE 23-34 Structures of olfactory receptor neurons.** Across a vast span of evolutionary distance—vertebrate, insect, nematode—olfactory receptor neurons have similar forms. Each has fine processes exposed to volatile odorants dissolved in fluid. Highly specific olfactory receptors (not shown) in the cells sense the odorants. The cells shown are not drawn to the same scale. [Adapted from F. Delcomyn, 1998, *Foundations of Neurobiology*, W. H. Freeman and Company, p. 327.]

▲ **FIGURE 23-35 The anatomy of olfaction in mouse and fly.** In both the mouse (a) and the fly (b), olfactory receptor neurons (ORNs) that express a single type of receptor send their axons to the same glomerulus. In this figure the red and blue colors represent the neural connections for two distinct expressed receptors. In the mouse the glomeruli are located in the olfactory bulb; in the fly they are in the

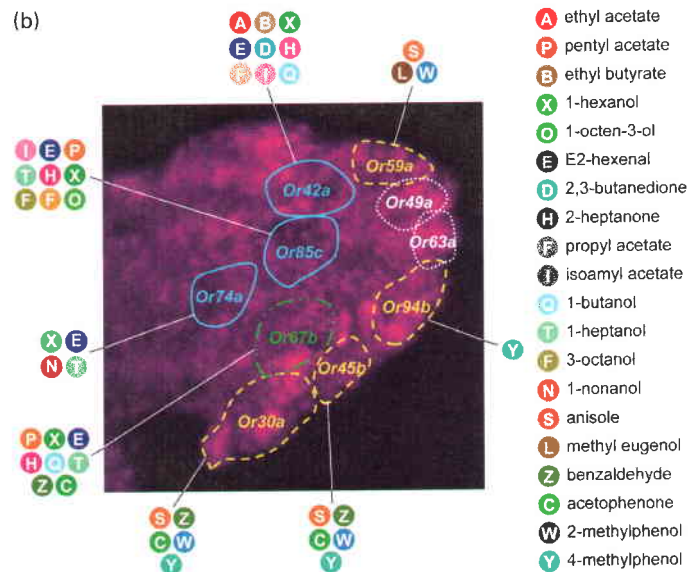

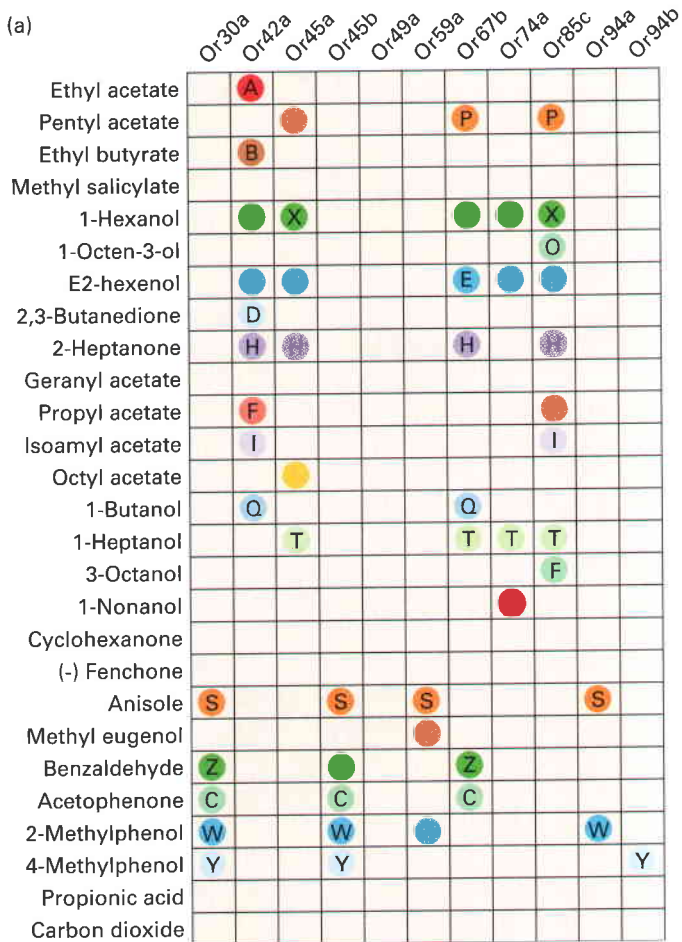

brain. In the glomeruli, the ORNs synapse with *projection neurons* in the fly, or *mitral neurons* in mammals. Each projection neuron (or mitral neuron) has its dendrites in a single glomerulus, thus carrying to higher centers of the brain information about a particular odorant. [From T. Komiyama and L. Luo, 2005, *Curr. Opin. Neurobiol.* **16**:67–73.]

species (see Figure 23-33; the black residues are highly variable). The solution to the second problem, the expression of a single olfactory receptor gene, has been explored using transgenic mice, but the mechanism is still not understood. When an engineered olfactory receptor gene is used to produce an olfactory receptor, other genes are turned off transcriptionally owing to some type of feedback regulation. If an engineered olfactory receptor gene is expressed that produces a reporter protein—not an olfactory receptor protein—then other genes can still be expressed. The feedback system must involve detection of the presence of a functional olfactory receptor protein.

The third problem, how the system is wired so the brain can understand which odor has been detected, has been partly answered. First, ORNs that have expressed the same

receptor send their axons to the same glomerulus. Thus all cells that respond to the same odorant send processes to the same destination. This convergence process could be due to (1) an attractive signal that somehow is specific for a certain olfactory receptor or (2) to mutual recognition, and subsequent coordinate growth, of axons that have the same receptor on their surface or (3) to a pruning process in which many connections are made but only those that share the same olfactory receptor persist, possibly regulated by neuronal activity. Developmental analyses show that ORN axons do *not* arrive at a glomerular “blank slate.” Rather the glomerulus has organized its projection neurons prior to the arrival of ORN axons. The system is to some degree hardwired.

In mice a crucial clue about the patterning of the olfactory system came from the discovery that olfactory receptors play

two roles in ORNs: odorant binding and, during development, axon guidance. Multiple ORN axons expressing the same receptor are guided to the same glomerulus destination. The full mechanism is not known, but it is clear that ORN axons respond both to their own olfactory receptor and to standard axon guidance molecules used in other parts of the nervous system. We will discuss those in the next section.

◀ **EXPERIMENTAL FIGURE 23-36 Individual olfactory receptor types can be experimentally linked to various odorants and traced to specific glomeruli in the *Drosophila* larval olfactory system.** (a) The different olfactory receptor proteins are listed across the top, and the 27 odorants tested are shown down the *left side*. Colored dots indicate strong odor responses. Note that some odorants stimulate multiple receptors (e.g., pentyl acetate), while others (e.g., ethyl butyrate) act on only a single receptor. Note that many receptors, such as Or42a or Or67b, respond primarily to aliphatic compounds, whereas others, such as Or30a and Or59a, respond to aromatic compounds. (b) Spatial map of olfactory information in glomeruli of the *Drosophila* larval brain. The mapping was done by expressing a reporter gene under the control of each of the relevant olfactory receptor neurons. The photograph indicates the glomeruli that receive projections from ORNs producing each of the ten indicated receptor protein types (Or42a, etc.). Also indicated are the odorants to which each receptor responds strongly. Note that with one exception (Or30a and Or45b) each glomerulus has unique sensory capacities. The exception might not be an exception if more olfactory gene expression patterns were tested. Glomeruli sensing odorants that are chemically similar tend to be situated next to one another. For example, the three glomeruli indicated by a blue solid line sense linear aliphatic compounds; those with yellow dashed lines, aromatic compounds. [Part (a) From S. A. Kreher, J. Y. Kwon, and J. R. Carlson, 2005, *Neuron* 46:445–456. Part (b): Courtesy of Jae Young Kwon, Scott Kreher, and John Carlson.]

KEY CONCEPTS OF SECTION 23.4

Sensational Cells: Seeing, Feeling, Hearing, Tasting, and Smelling

- Eyes focus light on a light-sensitive surface, the retina, where two types of photoreceptor cells are located. Highly sensitive rod cells (for black, gray, and white) and less sensitive cone cells (for color) are stimulated to produce electrical signals in response to light (see Figure 23-24).
- Stimulated photoreceptor cells hyperpolarize, rather than depolarize like most neurons.
- Light-sensitive pigments called *opsins* and *rhodopsins* give photoreceptor cells the machinery to perceive light (see Figure 23-25).
- Combined signals from multiple photoreceptor cells are interpreted together to discern patterns of light and dark. Retinal ganglion cells, which carry signals from the retina to higher parts of the brain, are responsive to sets of photoreceptor cells in patterns of dark center and light surround or vice versa (see Figure 23-26).
- The initial simple center-surround patterns are combined by higher-level cells to give increasingly complex images of the world (see Figure 23-28).
- Mechanosensory cells in mammals detect body position (proprioception), pain, heat, cold, touch, and pressure. The signals generated by these receptors give rise to maps of the body on the surface of the brain, called *homunculi* (see Figure 23-29).
- The inner ear senses motion and allows balance to be maintained, and detects sound (see Figure 23-30). The sound detector is the cochlea, with the organ of Corti inside. Vibrations

carried by small bones from the outer to inner ear move fluid, which in turn moves fine hairs called *stereocilia* (see Figure 23-31). The movements of these cilia generate receptor potentials in the hair cells, which are perceived as sound.

- A small number of taste receptors detect chemicals dissolved in saliva. Some are seven-transmembrane-domain proteins, and these work in different homo- and heterodimeric combinations to detect different tastes (see Figure 23-32).

- Odorant receptors, which are seven-transmembrane G protein-coupled receptors, are encoded by a very large set of genes. Any one olfactory receptor neuron expresses one and only one olfactory receptor gene, so a signal from that cell to the brain unambiguously conveys the nature of the chemical sensed. ORNs that express the same receptor gene send their axons to the same destination in the brain (see Figures 23-33 to 23-36).

▲ **FIGURE 23-37 Growth cones.** Growth cones have a broad spread of flattened material called the *lamellipodium*, from which many sharp spikes, called *filopodia*, protrude. [From E. W. Bent and F. B. Gertler, 2003, *Neuron* 40:209–227.]

23.5 The Path to Success: Controlling Axon Growth and Targeting

At the heart of the functions of the nervous system, especially the advanced functions, is complex circuitry. Having described the properties of nerve cells, electrical signal transduction, chemical transduction at synapses, and sensory cells, we now turn to the problem of how the connections between neurons are formed. Neural development can be viewed as having several steps: the formation of germinal zones where new neurons are born from stem cells, the determination of newly formed cells into neurons or glia, cell migration, axon and dendrite formation, growth of axons following guidance cues (sometimes over long distances), formation of synapses, pruning of exuberant connections, and the programmed death of some neurons.

A neural precursor cell often is unspectacular in appearance, a simple round cell. The growth of dendrites and axons is transforming. Axons grow in response to guidance systems, using signals from other cells. The leading, growing, end of an axon is called the **growth cone**. Signaling molecules bind to receptors at the growth cone, influence the cytoskeleton inside, and cause the growth cone to turn toward or away from the signal. The growth cone is a sensor and explorer.

From the functional point of view, the growth cone may be regarded as a sort of club or battering ram, endowed with exquisite chemical sensitiveness, with rapid amoeboid movements, and with a certain impulsive force, thanks to which it is able to press forward and overcome obstacles met in its way, forcing cellular interstices until it arrives at its destination.

—Ramón y Cajal, 1890, ref. in M. J. Zigmond et al., eds., 1999, *Fundamental Neuroscience*, Academic Press, chap. 18, p.519 [Cajal, S. R. y, 1890, À quelle époque apparaissent les expansions des cellules nerveuses de la moëlle épinière du poulet? *Anatomomischer Anzeiger* 21–22:609–639.]

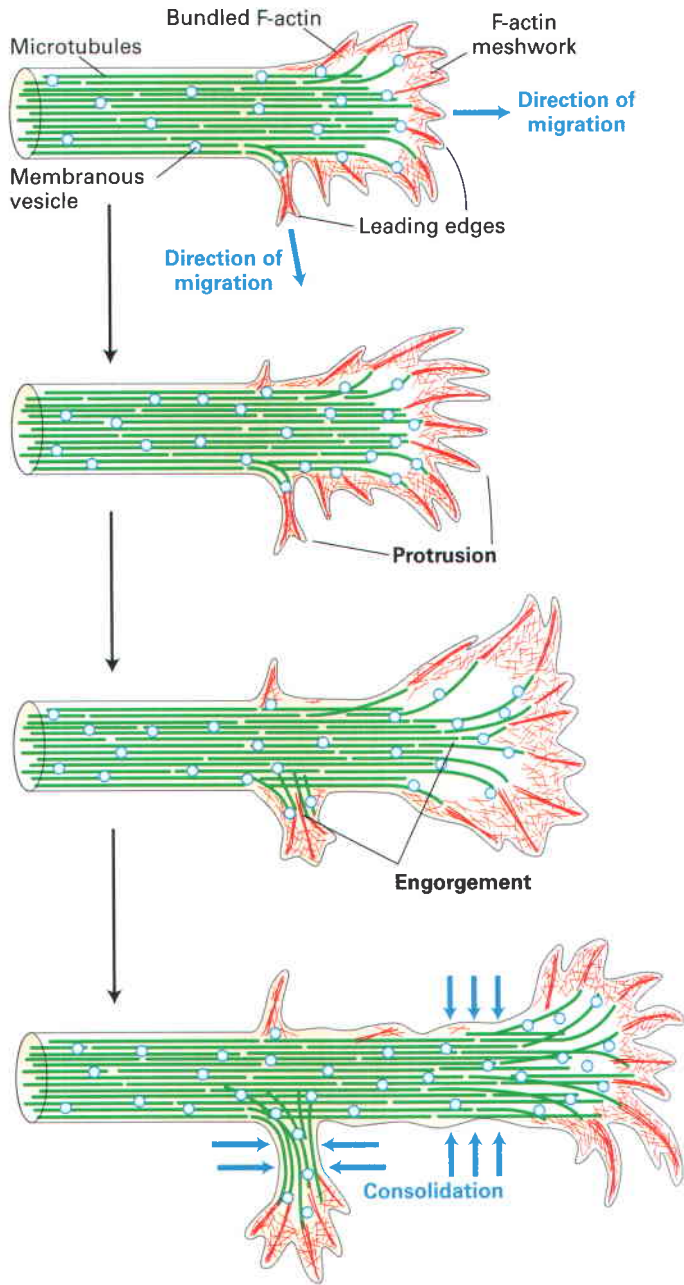

In this section we focus on the formation and growth of axons, and the guidance systems that allow axons to extend toward

targets and then recognize and synapse with the targets upon arrival. The growth cone is the heart of the matter, a cell extension that leads the elongating axon through its twists and turns. The amoeboid behavior of the growth cone was correctly described by Ramón y Cajal in 1890, and now we know a bit more about the molecules that give the cone its remarkable properties. The growth cone responds to signals that bias its direction of growth, thus wiring the nervous system.

The Growth Cone Is a Motorized Sensory Guidance Structure

The shapes of growth cones vary widely, but generally there are two major features: a broad spread of flattened material, the *lamellipodium*, and from it an extension of multiple sharp spikes called *filopodia* (Figure 23-37). The lamellipodium is typically on the order of 10–100 μm in breadth, the filopodia up to 20 μm long. As the growth cone moves away from the cell body, it leaves a tapering region behind that will be the shaft of the axon. Time-lapse studies show that as the growth cone advances, the filopodia that are located at the front move around the sides of the lamellipodium and retract at the back of the growth cone, where it is in the process of becoming an axon.

Three phases of growth-cone extension have been defined: protrusion, engorgement, and consolidation (Figure 23-38). *Protrusion* is the extension of lamellipodia and filopodia, *engorgement* is the swelling of both as the growth cone engulfs them, and *consolidation* is the active narrowing of the growth cone as it becomes the shaft of the axon. These three steps occur continuously as the growth-cone leading edge advances. Drugs that inhibit cytoskeletal elements have been used to investigate contributions of fiber systems to the three steps. Actin polymerization is required for protrusion and maintenance of the growth cone; cytochalasin B, which causes actin depolymerization (Chapter 17), led to retraction or misdirection of growth cones. Both lamellipodia and filopodia are formed by polymerization of actin. Microtubules form the backbone of the axon; colchicine, which causes microtubule depolymerization (Chapter 18), led to axon retraction but did not immediately perturb growth cones. Colchicine also caused the

▲ FIGURE 23-38 The advance of the growth cone. During protrusion, filopodia and lamellipodia extend under pressure from intracellular F-actin meshworks and elongated bundles (ribs). During engorgement, microtubules are elongated into the protrusions and carry membrane-bound organelles into them. During consolidation, depolymerization of actin in the growth-cone neck is followed by narrowing of the cell around the microtubule bundle to form the axon shaft. A new protrusion can form by branching off the side of a cylindrical axon shaft. [From E. W. Bent and F. B. Gertler, 2003, *Neuron* 40:209–227.]

appearance of extra outgrowths of lamellipodia and filopodia along the axon shaft, implying that microtubules may normally prevent the assembly of microfilaments in the axon.

The concentration of actin in the periphery and leading edge of the growth cone, and of microtubules in the more central and lagging regions, reflects the different roles played by the two (Figure 23-39; see also Chapter 17). Actin is

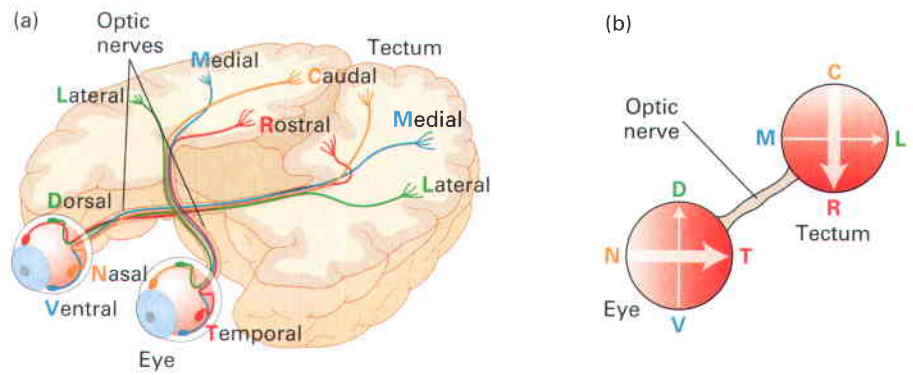

▲ EXPERIMENTAL FIGURE 23-39 Antibody labeling reveals cytoskeleton components inside cultured hippocampal growth cones. A single growth cone is shown three times, in each case labeled with an antibody for a different structure: F-actin, tyrosinylated microtubules (tyr-MTs), and acetylated microtubules (ace-MTs). The fourth panel shows a composite of the other three. Note the relative lack of microtubules at the leading edges and periphery, and the concentration of actin there. The microtubules are concentrated in the central region (although some tyr-MTs colocalize with actin bundle spikes in the peripheral region). The growth cone is paused, so the microtubules loop. [From E. W. Bent and F. B. Gertler, 2003, *Neuron* 40:209–227.]

assembled into filaments in the leading cone, the filamentous mesh of actin flows backward as the cone advances, and actin is disassembled as the cone transforms into an axon. The transport of actin toward the rear occurs in the filopodia and lamellipodia and is driven by a myosin motor. Note that this is completely different from treadmilling (Chapter 17). Movement of the actin mesh with respect to the growth cone involves movement of the entire filament at 1–7 $\mu\text{m}/\text{min}$, attached to myosin motors. For a filopodium to advance, the rate of actin polymerization at the leading edge must exceed the rate of retrograde flow.

Actin filaments have been viewed as major determinants in turning growth cones, a process that is crucial for the neuron to respond to guiding signals. Microtubules are also involved, since microtubule-inhibiting drugs prevent turning as well. Microtubules are assembled at the neuron's centrosome and transported by dynein motors toward the advancing growth cone, with the plus end leading. While traveling, the microtubules

► **FIGURE 23-40 The retinotectal maps.**

(a) The dorsal retina is connected to the lateral tectum on the opposite side of the brain, and the ventral retina is connected to medial tectum on the opposite side. Similarly the temporal-nasal (T-N) axis of the eye is reflected in the rostral-caudal (R-C) map of the tectum. (b) The maps of the visual world on the retina and the corresponding tectum are turned 90 degrees but otherwise are in register. The arrow shows how a pattern of light on the retina is reproduced as a set of retinal ganglion cell connections in the tectum. The tectum in mammals is referred to as the *superior colliculus (SC)* [G. Lemke and M. Reber, 2005, *Ann. Rev. Cell Dev. Biol.* **21**:551–580.]

can undergo polymerization and depolymerization. A tyrosinated form of tubulin is preferentially present in more advanced parts of the growth cone, while acetylated tubulin is enriched in central and lagging parts and in the axon itself (see Figure 23-39). The roles of such post-translational modifications are described in Chapter 2. An ordered process of tubule assembly and modification underlies growth-cone advancement.

As we have seen (Chapter 17), actin polymerization is controlled by a startlingly large set of regulatory proteins. More than 20 actin-binding proteins have been found in growth cones, most of which control nucleation or polymerization of actin filaments, or tether the filaments to the membrane. Many of these actin-binding proteins are targets of signal transduction events triggered by axon guidance signals, as we shall see in the next section.

The Retinotectal Map Revealed an Ordered System of Axon Connections

Researchers long debated two general ideas about how neurons might get wired. One, the “*resonance hypothesis*,” proposed that cells extend axons along pathways that are defined by mechanical forces. After many paths are taken and connections formed, the ones that work are preserved while others are removed. The second idea, a “*specific pathways hypothesis*,” suggested that axons choose their path by chemical affinity, molecules on the growing axons contacting molecules along the way that provide guideposts or signals. In 1963 Roger Sperry proposed a version of the specific pathways idea called the “*chemoaffinity hypothesis*.” He suggested that growth cones would find their way following molecular cues that form a gradient from start to destination, a seminal proposal that could not be properly tested for decades. Sperry’s proposal was based on his studies of how the axons of the retinal ganglion cells, which form the optic nerve, are arranged when they arrive at the *optic tectum*. The optic tectum is located in the roof of the midbrain and is the destination of retinal ganglion cell axons that grow from the retina. The incoming retinal neurons form a map on the tectum (the **retinotectal map**) that reflects the arrangement of rods and cones in the retina, and indeed the visual world outside (Figure 23-40). The spatial map on the retina is in essence copied into the brain.

Sperry performed experiments with the frog eye and brain to distinguish the two models, “resonance” versus “chemoaffinity,” that describe how axons may accomplish this mapping (Figure 23-41). The frog optic nerve will regenerate if it is severed, and the pattern of regeneration—the route-finding by axons—is revealing about how axons are guided. In the normal arrangement, retinal ganglion cell axons from the ventral part of the eye connect to the medial part of the tectum, while axons from the dorsal part of the eye connect to the lateral tectum (see Figure 23-41a). For each eye, the connections are made on the opposite side of the brain, left eye to right brain and right eye to left brain. Sperry next added a second surgery to the experiment, rotating one eye 180 degrees, so that ventral and dorsal are reversed (Figure 23-41b). If the resonance hypothesis is correct, i.e., mechanical forces followed by a functional sorting-out process were governing regeneration, the visual system should end up functioning normally, since the proper connections will be established and maintained (Figure 23-41c, *left*). If there is a chemoaffinity guidance system, then vision should be inverted because despite the rotation the ventral axons would find their way to the lateral tectum and the dorsal ones to the medial tectum (Figure 23-41c, *right*). In this case the inverted eye would lead to the frog’s having inverted vision: it would see something above and would think it was below (Figure 23-41d). The results were clear: after regeneration the frog responded to a fly passing above by shooting its tongue *down*. The axons were originating from abnormal locations yet finding their way to the right connections, so the inverted eye was tricking the frog’s brain. The chemoaffinity hypothesis was affirmed.

It seems a necessary conclusion...that the cells and fibers of the brain and cord must carry some kind of individual identification tags, presumably cytochemical in nature, by which they are distinguished one from another almost, in many regions, to the level of the single neuron.
—Roger Sperry, 1963

There is now substantial evidence that Sperry’s general ideas were correct. Nonetheless much remains to be learned about how the enormous complexity of the neural circuitry is successfully assembled. The relative importance of local versus

◀ **EXPERIMENTAL FIGURE 23-41 Eye rotation experiments test the properties of axon pathfinding.** (a) Normal projection of nerves, from dorsal (D) eye to lateral (L) tectum and ventral (V) eye to medial (M) tectum. (b) Schematic representation of two sequential operations, (1) a severing of the optic nerve and (2) a 180° rotation of the eye (or no rotation in the control experiment). Regeneration of the nerves was then allowed to occur. Note that in the rotated left eye, the dark-shaded half, now oriented dorsally (D), nevertheless still contains the ventral retina, as seen in (a). Likewise the light half of the eye, which encompasses the dorsal retina, is now oriented ventrally (V). (c) Two possible outcomes, depending on which hypothesis is correct. The resonance hypothesis predicts X: vision is restored because function selects proper connections. The specific axon pathway hypothesis predicts Y: vision is inverted because dorsal retinal axons still go to lateral tectum because of chemical affinity specified, even though the dorsal retina is now located in the ventral position. (d) The results support hypothesis Y; the frog's vision is inverted.

There Are Four Families of Axon Guidance Molecules

For many years, attempts were made to identify key axon guidance molecules. Approaches included making panels of antibodies against surface molecules, culturing neurons and testing extracts for their ability to make growth cones turn, and using genetics to identify mutants that fail to properly wire the nervous system. All these attempts worked to a degree, but genetics was the most powerful approach, since it identified previously unknown molecules while at the same time convincingly demonstrating their importance in vivo.

We can set a high standard for what constitutes a proper guidance molecule: it must be produced by cells that actually guide neurons in vivo, it must be necessary for guidance, the guided cells must have sensors and signal-transduction machinery for responding, and the mislocalization of the signal must cause cells to turn the wrong way.

We will discuss here four families of proteins (Figure 23-42) that fulfill our criteria and, with their receptors, provide crucial information to growing axons: **Ephrins**, **Semaphorins**, **Netrins**, and two related proteins called **Robo** and **Slit**. These proteins have both attractive and repulsive effects on growing axons. Since the growth cone is an active *sender* of signals, as well, the communication is mutual. After the initial connections form, the wiring is refined by preserving connections that work and discarding those that do not contribute to neural function. Many cells that fail to make useful connections die by apoptosis.

Ephrins The retinotectal map described above is a striking example of the simplicity of the nervous system, which belies the seemingly chaotic mass of neurons in the visual part of the brain. This rather amazing phenomenon is due in part to a remarkable signaling system involving the **ephrins**, a family of cell-surface signaling proteins, and their receptors, the **Ephs**. (The word “Eph” comes from the *erythropoietin-producing hepatocellular carcinoma* cell line where the proteins were originally found.) Ephs constitute the largest family of receptor tyrosine kinases (RTKs; Chapter 16), with 14 Ephs and 8 ephrins in mice. Although Ephs usually serve as receptors for ephrins,

long-range signaling, the roles of glia, the influences of neural electrical activity, and the signal transduction and cytoskeletal changes that form the response to signals are important areas of current research. The lure of this field is substantial, since understanding how neurons are wired to one another underlies the working of the brain and at the same time is important for learning how to stimulate repair of damaged neural circuits.

► **FIGURE 23-42 Families of guidance molecules.**

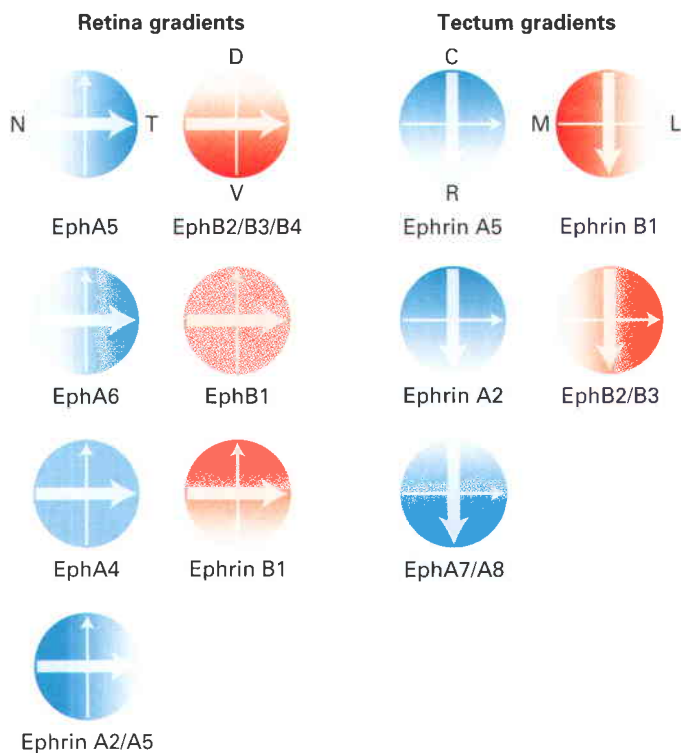

Four major families of signaling proteins provide crucial information to direct growing axons. The ligands (a) are Netrins, Robo/Slit, Semaphorin, and Ephrin proteins. The receptors (b) are as follows: Netrin interacts with its receptor DCC in vertebrates; the corresponding but different receptor in nematodes is called Unc5. Both contain immunoglobulin (Ig) domains (blue crescents) and a variety of other domains as shown. The Slit ligand interacts with the Robo receptor, which also has Ig domains. The Semaphorins interact with diverse receptors, generically called Plexins. Some of the interactions are through “sema” domains (red bars), present in both ligand and receptor, others require Ig domains. Ephrin ligands interact with Eph receptors, although signaling appears to go in both directions and in some cases the Ephrins act more like receptors. All of the receptors have single transmembrane domains. The Netrin and Slit ligands are secreted and not membrane associated. The Semaphorin ligands can associate with membranes to varying degrees—some not at all. The Ephrins are membrane-associated. See the text for a detailed discussion of these four families. In addition to these four families of proteins a few others, including the developmental regulators Wnt and Shh, contribute additional guidance information. [From R.P. Kruger, J. Aurandt, and K.-L. Guan, 2005, *Nature Rev. Mol. Cell Biol.* 6:789–800, and B.J. Dickson, 2002, *Science* 298:1959.]

in some cell types signaling can go from an Eph-bearing in the other direction to an ephrin-bearing cell. In retinotectal map development, most signaling is from ephrin to Eph receptor. Each Eph receptor specifically binds one or a few ephrins. Ephs and one class of ephrins, the A class, are joined to cell-surface membranes by GPI links. Ephrin Bs, the other class of ephrins, are transmembrane proteins (see Figure 23-42). The ephrin proteins affect cell migration, axon guidance, synapse development, and vascular development, but we will focus on their roles in guidance and formation of the retinotectal map.

Ephs and ephrins are distributed in gradients so that advancing axons can recognize and grow toward appropriate targets. Antibodies against ephrin A5 show a gradient of protein with the highest levels in the anterior. Mice lacking ephrin A5 have guidance defects; axons that should have been targeting anterior tectum grow into posterior regions. Further investigations showed that cells express Eph receptor proteins in two orthogonal gradients, to control axon

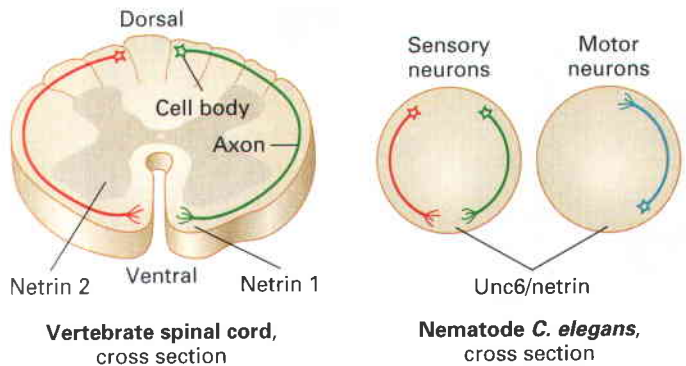

guidance along each of the two axes (Figure 23-43). In each axis, the graded amount of receptor in retinal ganglion cells confers differential sensitivity to specific ephrins emitted from the tectum targets. The EphA's and ephrin A's controlling one axis do not cross-react with the EphB's and ephrin B's for the other axis. Therefore, axons can “learn” their positions on an XY coordinate system by reading levels of ligand for which they have receptors. To give one example, axons that have EphB2, 3, and 4 receptors are attracted to places where there are high levels of ephrin B1 ligands, so axons originating in ventral retina tend to go to medial tectum. The full situation with all these gradients is more complex and not yet fully understood. Eph tyrosine kinase signal transduction influences the small GTPases Rho, Cdc42, and Rac, thus regulating assembly of the actin cytoskeleton and controlling guidance of the growth cone. The activation of an Eph receptor may cause attraction or repulsion of a growth cone, depending on the cell.

▲ FIGURE 23-43 Gradients of Eph proteins form two orthogonal signaling systems. Eph receptor gradients in the retina are shown on the *left*; ephrin gradients in the superior colliculus (tectum), on the *right*. Gradients along the nasal-temporal (retina) and rostral-caudal (tectum) axes are shown in blue; gradients along the dorsal-ventral (retina) and lateral-medial (tectum) axes are shown in red. The more color, the more protein present. The white arrows and arrow outlines indicate how the maps are related (see Figure 23-40). Ephrin A's are chemorepellent for EphA-expressing axons, so retinal ganglion cells carrying Eph A receptors tend to go from their origins at the temporal side of the retina to destinations in the rostral tectum, where the concentration of ephrin A's is lower.

Semaphorins Semaphorins are a diverse family (see Figure 23-42), and much remains to be learned about all their effects. They were named for the alphabetic signaling system of flags that was used to communicate over long distances. Semaphore signals can spell out any message, but in the nervous system semaphorins largely carry a single message: go away. They are potent repellents. The family of two invertebrate and five vertebrate semaphorin glycoproteins (Figure 23-42) includes some that are secreted and some that are membrane-bound. This implies that some of them act on adjacent cells, while others have a longer reach. Motor, sensory, olfactory, and hippocampal neurons can be repulsed by semaphorin signals. Semaphorins bind to receptors called **plexins** that are single-pass transmembrane proteins. The overall picture is of receptor proteins capable of acting as scaffolds both inside the cell and outside, assembling protein complexes and modifying their activities. How exactly this modifies growth-cone advancement is an area of current research; at least part of the answer is differential adhesion to cells on one side of the growth cone versus the other.

Netrins Netrins are secreted proteins related to laminin (see Figure 23-42). They were discovered in genetic screens look-

▲ FIGURE 23-44 Evolutionary conservation of netrin signaling. In the vertebrate spinal cord, commissural neurons with cell bodies in dorsal regions grow axons toward the ventral midline, attracted by netrin signals. In the worm *C. elegans*, sensory neurons follow a similar path toward ventral Unc6/Netrin, while motor neurons follow the opposite path away from Unc6/Netrin. Certain vertebrate axons are also repelled by netrins. Netrins were discovered in worms via mutations that altered the pathfinding by sensory neurons, and in vertebrates as secreted molecules that could influence pathfinding of commissural neurons in spinal cord explants.

ing for misrouting of neurons in *C. elegans*, the nematode worm for which every cell and every neuron has been identified. About 30 genes were found, three of which affected dorsal-ventral routing of the sensory and muscle neurons (Figure 23-44): *unc-6*, which encodes a netrin protein; *unc-40*, which encodes the netrin receptor (called *DCC* in mammals); and *unc-5*, which encodes a second type of netrin receptor. *Unc-6/Netrin* mutations affected both dorsally directed and ventrally directed axon extensions. Vertebrate netrins were found in studies of how commissural (crossing) neurons find their way through the spinal cord (see Figure 23-44). These neurons emerge from dorsal regions of the spinal cord and extend around the periphery of the cord toward the ventral midline.

To test for the presence of guidance molecules, parts of the spinal cord were cultured either separately or together. When the most dorsal part was cultured near a ventral part, axons grew out toward the ventral tissues. No axon outgrowth was observed when the two parts were cultured separately. Extracts from the ventral part had the same activity, stimulating axon outgrowth from dorsal tissue. A heroic protein purification, starting with about 20,000 embryonic chick brains, succeeded in identifying two proteins that were potent chemoattractant signals. Both were netrins. Netrin 1 is highly expressed in the spinal cord floor plate, the most ventral part. Further proof of the role of netrins came from mouse gene knockouts, in which the commissural neurons were unable to properly find their way (Figure 23-45). Netrins guide axons to the ventral midline in nematodes, flies, and vertebrates, an example of evolutionary conservation of protein function over more than half a billion years.

A puzzle remained. The worm version of the protein appeared to have two functions: attracting the axons of sensory neurons to grow toward the ventral midline and driving the axons of motor neurons *away* from the ventral midline. The simplest possibility was that netrin is attractive to some axons and repellent to others. Indeed evidence quickly emerged

▲ EXPERIMENTAL FIGURE 23-45 Mouse *netrin* $-/-$ mutants have commissural neuron guidance defects. (a) Wild-type tracing of commissural neurons (red) that originate dorsally (top) and grow toward and across the ventral midline (green arrowheads) under the influence of netrin produced by ventral midline (floor plate) cells. (b) Homozygous *netrin* $-/-$ mouse mutant. Many commissural neurons wander off track (green arrows) before reaching the ventral regions, and others (green arrowheads) turn instead of crossing the ventral midline. [Courtesy of Marc Tessier-Lavigne, Genentech Inc.]

that certain vertebrate neurons found netrin repulsive. Genetic analyses in worms showed that Unc-40 receptor is required for attraction by netrin, while Unc-5 receptor in combination with Unc-40 is required for repulsion by netrin.

Another puzzle remained. If the axons of commissural neurons are attracted by netrin coming from the ventral midline, how do the axons continue to grow after they have crossed the midline? One would expect them to turn around and go right back. The solution to this puzzle awaited the discovery of still other key players in axon guidance, Slit, Robo, and Comm.

Robo and Slit Guidance Molecules The path of growing axons in the insect nerve cord is reminiscent of a subway map (Figure 23-46a). Genetics allowed the discovery of guidance genes and proteins that affect the pathfinding process, changing the map. A large set of random mutations was introduced into the *Drosophila* genome to generate lethal mutations. The mutations could be carried in heterozygotes, and when the heterozygotes of each line were crossed, a quarter of their progeny were homozygous for the newly induced mutation. These progeny were stained to show the embryonic nerve cord, the equivalent of our spinal cord, which in the wild type looks like a ladder (Figure 23-46b). In lines of flies where the mutation was in a gene necessary for axon guidance, defects in the nerve cord could be seen. Among the genes identified in this manner were three, *slit*, *roundabout* (*robo*), and *commissureless* (*comm*). They defined yet another set of critically important and evolutionarily conserved axon guidance molecules.

Slit is a secreted protein (see Figure 23-42) made by midline glia. The Slit receptor is Robo, a single-pass transmembrane protein with only a short sequence in the cytoplasm and fibronectin and immunoglobulin domains on the outside of the plasma membrane (see Figure 23-42). The Robo/Slit complex is a chemorepellent interaction. The presence of Slit in the midline serves to repel axons containing Robo receptors, thereby ensuring that ipsilateral (same-side) neurons do not cross to the opposite side. In loss-of-function

slit mutants, or in double mutants that lack two *Drosophila robo* genes, axons go to the midline but can never leave (Figure 23-46c, d). This can be explained by the fact that, in the absence of Robo receptor or its ligand, the chemorepellent Robo/Slit interaction at the midline does not occur.

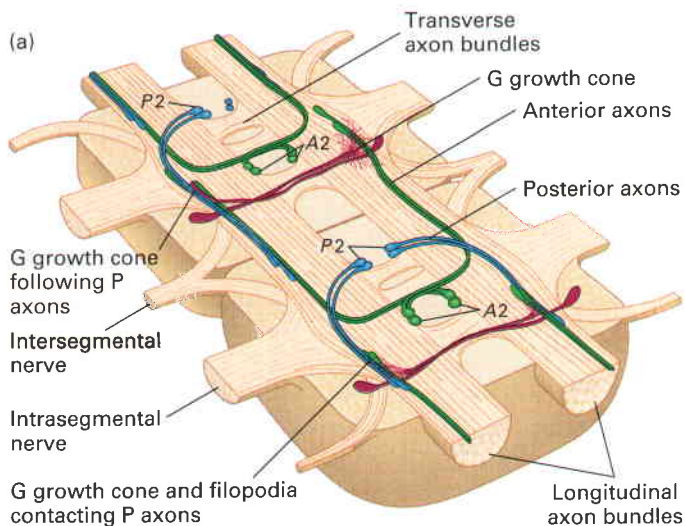

This raises the question of how an axon that needs to cross the midline is first attracted to it and then repelled from it. An axon that will cross the midline does produce Robo protein and should be repelled by Slit, but the axon is initially refractory to the Slit signal because the Robo protein is trapped in the Golgi network by a Golgi protein called Commissureless (*Comm*) and never reaches the cell membrane. Once the axon reaches the midline, *Comm* becomes inactive and Robo reaches the surface again. The newly accessible receptor allows a response to midline Slit, and the axon grows away from the midline on the far side. Loss of *comm* function allows excessive Robo to reach the surface, so no axons cross the midline (Figure 23-46e). The expression of *comm* is normally regulated so that it is “off” in cells whose axons are supposed to remain in only the left or right longitudinal axon tract, and is “on” in cells whose axons must cross to the other side.

None of these protein guidance systems is dedicated solely to the nervous system; in fact, all of them are employed in other tissues for various purposes. Indeed most of the special attributes of neural cells appear to be more or less exaggerated versions of processes common to many or all cells. That is apparent (1) in the polarization of neurons from dendrite to axon, which employs cell-asymmetry proteins, (2) in the neuronal intracellular organelle-transport systems, which depend on variations of endo- and exocytosis, (3) in outgrowths of axons and dendrites, which have features of chemotaxis, and (4) in the use of channel proteins to control ion flow. Neurons are a variation on familiar cell biology themes, a variation with enormous functional power.

Developmental Regulators Also Guide Axons

In Chapter 22 we became familiar with a set of secreted signaling proteins that control cell fates and, in some cases, cell division. Since these were discovered for their roles in development and differentiation, they were not initially suspects in the hunt for axon guidance molecules. Yet it turns out that at least three cell fate regulators, Hedgehog (specifically Sonic hedgehog, *Shh*), BMP, and Wnt proteins, can also be axon guidance molecules. This is in a sense reassuring, as the sum total of complexity of the other guidance molecules still seems rather low compared with the challenge of routing millions of axons on complex paths.

In the developing spinal cord (see Figure 23-44), even in the absence of Netrin 1 some commissural axons still extend toward the ventral midline. Another protein, *Shh*, made in the floor plate, accounts for that remaining guidance activity. Proof of its role came from the discovery that (1) cultured cells that secrete *Shh* reorient commissural axons in tissue explants, (2) isolated neurons in culture turn toward a source of pure *Shh* protein, and (3) mutants affecting *Shh* signal transduction interfere with axon pathfinding. Thus commissural axons are guided toward the ventral midline by both Netrin

◀ **FIGURE 23-46 Phenotypes of mutations in axon guidance mutants in the insect nerve cord.** (a) This diagram shows examples of the paths taken by neurons that cross and form the commissures. Commissures are the “rungs of the ladder” which are connected by longitudinal axon bundles. The diagram was constructed from studies of axon growth in the grasshopper, where individual neurons can readily be identified and followed due to the large size of the embryo. For example the specific neurons A2 and P2, can be recognized and studied. The growth cones marked “G” (purple) can be recognized as following the axons of the “P” cells (blue). The circuitry is highly similar to that observed in the *Drosophila* embryo where genetic analyses have been used to identify molecules required for proper axon pathfinding (b-e). The brown-stained pattern of commissures in a *Drosophila* embryo can be used to detect mutants that do not properly carry out axon pathfinding. In (b) the wild-type pattern is seen. A few nuclei are stained blue in this panel to mark the midline. In (c-e) the nerve cords of embryos homozygous for three different mutations are shown. In each case there are dramatic failures of axon pathfinding. [(a) From C.S. Goodman and M. Bastiani. 1984. *Scientific American* **251**: 58. (b-e) From M. Seeger et al., 1993, *Neuron* **10**: 409-426]

Wild type

Each “contralateral” neuron sends an axon that crosses the midline once and only once.

slit

Axons collapse at the midline and never leave it.

roundabout (robo)

Many axons cross the midline more than once.

commissureless (comm)

Axons never cross the midline.

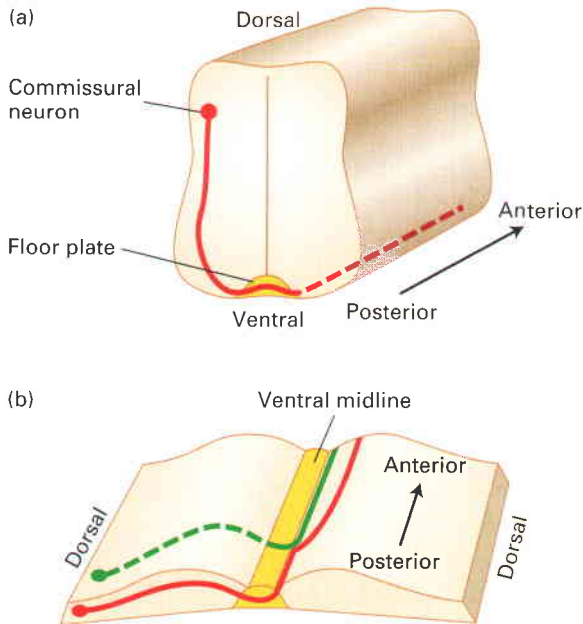

1 and Shh. Conversely, BMP proteins originating from dorsal regions repel commissural neurons. Mice mutant for certain BMP genes were found to have commissural axon guidance defects. Thus commissural neurons respond to “pulling” by Netrin 1 and Shh and “pushing” by BMPs.

In the developing spinal cord, after the axons of commissural neurons reach the ventral midline and cross it, they turn sharply toward the head (Figure 23-47). In fact, many axons must find their way along the anterior-posterior (A-P) axis (head to tail), but less is known about guidance in this dimension. Discoveries in *C. elegans*, *Drosophila*, and mice show that Wnt secreted-protein signals play an important role in A-P patterning. The use of a distinct signaling system for A-P versus D-V growth may prevent cells from getting confused about which axis is in play, when cells have to make decisions about both axes at the same time. *Wnt4* in particular is involved. It is expressed in a gradient in the neural tube floor plate, with the highest amount near the

head. Neurons in culture can be attracted to Wnt signals, and interference with Wnt signal transduction causes defects in the anterior migration of commissural neurons. Wnt signals are also involved in guiding the growth of retinal ganglion neurons toward the optic tectum (see Figure 23-40).

Axon Guidance Molecules Cause the Growth Cone to Turn

The growth cone is in essence an explorer, probing its neighborhood to make decisions about which way to extend the axon. In addition to the protein signals we have discussed, growth cones in culture can be attracted by neurotransmitters such as acetylcholine. Guidance molecules affect the growth cone by directly regulating the actin and microtubule cytoskeleton. Repulsive forces cause the growth cone to stop advancing, or cause it to turn away. Attractants stimulate the growth cone to keep moving in their direction.

▲ **FIGURE 23-47** Wnt signals control the anterior-posterior elongation of commissural neurons in the spinal cord. (a) The spinal cord of a 13-day-old rat embryo is shown with the path of a commissural neuron indicated in red. (b) "Open-book" view of the same path, but showing the different paths taken by (green) neurons that extend close to the midline and (red) neurons that take a more lateral path. Both respond to Wnt signals that are more anterior. [From A. Lyuksyutova et al., 2003, *Science* **302**:1984–1988.]

Turning of a growth cone is accomplished by causing filopodia or lamellipodia (or both) on one side of the cone to be more stable or to extend more vigorously, or conversely causing their collapse on the other side. How do all the guidance factors affect the growth cone? It is particularly important to understand how the growth cone responds to more than one guidance system at once, a fascinating problem in integrative molecular cell biology.

Ca^{2+} releases can strongly affect growth-cone behaviors. Dramatic changes in Ca^{2+} concentration occur over periods of less than a second (Figure 23-48), owing to the actions of

▲ **EXPERIMENTAL FIGURE 23-48** Ca^{2+} fluxes can be measured in a growth cone over time. (a) Ca-sensitive dye (Fluo-4) is used to observe changes in intracellular Ca^{2+} ; the Fura-Red dye is not Ca^{2+} -sensitive and serves as an internal control. Note the burst of Ca^{2+} in one of the filopodia. [From T. M. Gomez and J. Q. Zheng, 2006, *Nature Rev. Neurosci.* **7**:115–125.]

▲ **FIGURE 23-49** Semaphorins cause growth cones to turn away. Soluble semaphorins like Sema3A or semaphorins on glia cells like Sema4D act through plexin receptors and intracellular pathways to turn the growth cone. The asymmetry of the signals causes, on the "right" of this cell, detachment of the growth cone from integrin (due to Ras inactivation), destabilization of microtubules, and increased contraction of actomyosin (through Rho activation). Meanwhile on the "left" the lamellipodia extend under the influence of active Rac, and integrin attachments to the extracellular matrix form under the influence of activated Ras. [From R. P. Kruger, J. Aurandt, and K.-L. Guan, 2005, *Nature Rev. Cell Mol. Biol.* **6**:789–800.]

pumps, channels, and Ca-sequestering proteins. Ca^{2+} inhibits neurite outgrowth in general, so reducing global $[\text{Ca}^{2+}]$, especially for prolonged times, can stimulate outgrowth. More local and more subtle changes in calcium can influence directional growth. Local $[\text{Ca}^{2+}]$ increases generally occur on the side of the growth cone closest to an attractant.

Semaphorins and other repellents stimulate the collapse of growth cones by causing the depolymerization of actin (Figure 23-49). The disassembly of the cytoskeleton is triggered preferentially on the side of the cone nearest the signal. Concomitantly, interference with integrins on that side of the cell selectively allows part of the growth cone to break free

from extracellular matrix. Loss of actin appears to lead to a loss of microtubules where the growth cone abandons extension. Ephrin-dependent growth-cone repulsion depends on a series of steps that inactivate Rho and reduce actin assembly, therefore causing the growth cone to collapse.

KEY CONCEPTS OF SECTION 23.5

The Path to Success: Controlling Axon Growth and Targeting

- Growth cones are flattened fans called *lamellipodia* at the growing end of an axon (See Figure 23-37). They have small fingerlike protrusions called *filopodia*.
- Growth cones guide the growing axon and are therefore a major determinant of the initial pattern of wiring in the nervous system.
- The cytoskeleton that shapes the growth cone consists of a central bundle of microtubules immersed in a sea of shorter actin filaments (see Figure 23-38). Actin assembles into filaments at the growing tip of the growth cone and disassembles at the axon that forms after the growth cone has passed. Microtubules continue to extend during this process, to keep up with the advancing growth cone (see Figure 23-39).
- The spatial layout of light striking the retina is carried to the tectum, a visual part of the brain, and is represented as a map (see Figure 23-40). The retinal ganglion cells that connect retina to tectum maintain spatial order so that the map of the retina is aligned with the map in the tectum.
- Axons growing from retina to tectum follow guidance cues that inform as to medial-lateral and dorsal-ventral orientation (see Figure 23-41). The cues are provided by a variety of secreted and surface protein signals. Different strengths of binding between the surfaces of advancing growth cones and other neurons and the extracellular matrix influence the path chosen by growth cones.
- Four systems of guidance molecules have been identified (see Figure 23-42): ephrins and Ephs; semaphorins and plexins; netrins and DCC receptors; and Slits, Robos, and Comms. The multiple members of these protein families often make it difficult to precisely identify their functions. All the families have been highly conserved during evolution, and even some of their specific functions in development, like ventral midline axon growth guidance, have been conserved.
- Ephrins and Ephs are important in guiding retinal ganglion axons as they construct the retinotectal map (see Figure 23-43). Different classes of Eph proteins work in each of the two orthogonal axes, forming a two-dimensional system.
- Semaphorin signals, acting on their plexin receptors, have a repulsive effect on growth cones (see Figure 23-49).

- Netrin signals are usually attractive to growth cones that carry netrin receptors such as DCC, but netrins can also be repulsive signals (see Figure 23-44). Netrins guide commissural axons toward the ventral midline in the vertebrate spinal cord.

- Genetic screens led to finding Robo, Slit, and Comm proteins. Slit is a secreted signal that acts on Robo receptor, while Comm is a Golgi protein that controls whether Robo reaches the cell surface. Together they form a switch that allows axons to grow toward the midline, and subsequently grow away from it (see Figure 23-46).

- Three kinds of secreted proteins first identified as developmental regulators provide guidance functions: BMPs, Wnts, and Hedgehogs (see Figure 23-47).

- Axon guidance molecules, directly or indirectly, cause the growth cone to turn. Turning is the result of local effects of guidance factors on the membrane of the growth cone. The binding of a guidance signal can cause fluxes in calcium, changes in kinase and phosphatase activities, and differential activation of small GTPases like Rac that control cytoskeletal assembly (see Figure 23-49).

Perspectives for the Future

In this chapter we have provided an introduction to the remarkable properties of the nerve cells that serve as our interface with the world. We have seen how organelles and proteins—the universal systems of cell function—have become adapted to the special needs of neurons. The cytoskeleton shapes the cells, so that some are a meter long and others have enormously complex branched patterns. Transport processes and polarity control move organelles and macromolecules to their proper sites of action. Motors allow cells to migrate and extend processes. Signaling systems guide extending axons to their targets, including some signals that are also used in the development of many other tissues and organs. Cell-cell adhesion molecules provide selective and reversible contacts between cells. Most distinctively, channel proteins that probably evolved for import or export of metabolic molecules and for homeostatic control of ion concentrations have become adapted to the regulation of the electric properties of cells. Ligand- and voltage-gated channels create resting potentials and then allow unidirectional transmission of incredibly fast action potentials. The universal system of endocytosis and exocytosis has been adapted to the needs of chemical transduction across synapses. Other proteins have made sensory cells sensitive to light, touch, pain, sound, smell, and taste. Beyond the neurons themselves, glia provide insulation, stimulate synapse formation, and provide immune protection. Stem cells form neurons and glia initially, and some persist in the adult to allow continuing regeneration.

The advances in the cell biology of the nervous system have been paralleled by extraordinary advances in exploring

how neural circuitry carries out the interpretation of sensory information, analytical thought, feedback mechanisms for motor control, establishment and retrieval of memories, inheritance of instincts, regulated hormonal control, and emotional responses. Some experiments are done with noninvasive imaging technologies, observing thousands to millions of neurons and detecting global electrical activity. Others are done observing a few cells at a time using inserted electrodes. It is difficult to bring the global views together with the single-cell views, but there have been notable successes, as we have seen here for the center-surround processing of visual information. From the standpoint of molecular cell biology, some of the greatest excitement has been in the area of research into mechanisms of memory. In most cases memory does not depend on forming new neurons. Instead, existing neurons are modified. Changes in the number and strength of synapses often underlie the establishment and endurance of memories. Current studies are directed at the molecular changes that alter synapses, both in the pre- and postsynaptic cells. Thus a fascinating problem that would seem to involve intractable numbers of neurons has become approachable through the techniques of molecular cell biology. A full understanding of memory will require finding ways to connect the molecular cell biology with more precise information about global circuits. This is likely to be accomplished by improvements in imaging methods, invasive and noninvasive, combined with the development of better ways to manipulate the activities of single neurons, or of large numbers of neurons simultaneously. There is every reason to expect these advances to happen, an exciting prospect for understanding the brain and doing a better job of treating diseases that affect the nervous system.

Review the Concepts

1. What is the role of glial cells in the brain and other parts of the nervous system?
2. The resting potential of a neuron is -60 mV inside compared with outside the cell. How is the resting potential maintained in animal cells?
3. Name the three phases of an action potential. Describe for each the underlying molecular basis and the ion involved. Why is the term *voltage-gated channel* applied to Na^+ channels involved in the generation of an action potential?
4. Explain how the crystal structures of potassium ion channels suggest the way in which the voltage-sensing domains interact with other parts of the proteins to open and close the ion channels. How does this structure-function relationship apply to other voltage-gated ion channels?
5. Explain why the strength of an action potential doesn't decrease as it travels down an axon.
6. What prevents a nerve signal from traveling "backwards" toward the cell body?
7. Myelination increases the velocity of action potential propagation along an axon. What is myelination? Myelination causes clustering of voltage-gated Na^+ channels and Na^+/K^+ pumps at nodes of Ranvier along the axon. Predict the consequences to action potential propagation of increasing the spacing between nodes of Ranvier by a factor of 10.
8. Acetylcholine is a common neurotransmitter released at the synapse. Predict the consequences for muscle activation of decreased acetylcholine esterase activity at nerve-muscle synapses.
9. Following the arrival of an action potential in stimulated cells, synaptic vesicles rapidly fuse with the presynaptic membrane. This happens in less than 1 ms. What mechanisms allow this process to take place at such great speed?
10. Neurons, particularly those in the brain, receive multiple excitatory and inhibitory signals. What is the name of the extension of the neuron at which such signals are received? How does the neuron integrate these signals to determine whether or not to generate an action potential?
11. What is the role of dynamin in recycling synaptic vesicles? What evidence supports this?
12. When a rod or cone cell is stimulated by light, a cascade of events is set in motion, which eventually leads to the transmission of visual information to the brain. Outline the molecular steps in this cascade from light absorption by rhodopsin to hyperpolarization of a rod or cone cell membrane.
13. Which cells are involved in visual contrast detection? How do these cells integrate photoreceptor cell information to detect contrast?
14. Compare the structures and functions of the receptor molecules for salt and sour taste; the taste receptor molecules

for sweetness, bitterness, and umami; and odor receptor molecules.

15. How did Roger Sperry's experiments in frogs distinguish between the resonance hypothesis and the chemoaffinity hypothesis for how neurons become wired?

Analyze the Data

Olfaction occurs when volatile compounds bind to specific odorant receptors. In mammals, each olfactory receptor neuron in the olfactory nasal epithelium expresses a single type of odorant receptor. These odorant receptors constitute a large multigene family (>1000 members) of related proteins. Binding of odorant induces a signaling cascade that is mediated via a G protein, $G_{\alpha\text{olf}}$. Recent studies suggest that there are a small number of olfactory sensory neurons in the nasal epithelium that express members of the trace-amine associated receptor (TAAR) family, chemoreceptors that are G protein-coupled receptors (GPCRs) but are unrelated to classical odorant receptors (see Liberles and Buck, 2006, *Nature* 442:645–650). The mouse genome encodes 15 TAAR genes while the human genome encodes 6.

a. In order to examine the expression pattern of different TAARs in the olfactory nasal epithelium, researchers localized TAAR RNA by in situ hybridization in pairwise combinations. All possible pairwise combinations of the 15 mouse TAARs were examined. A typical example of the results obtained is shown in the top set of panels in the figure below in which TAAR6 and TAAR7 have been localized with fluorescent probes in the nasal epithelium of mouse. The Taar6 probe was labeled with a green fluor, the TAAR7 probe with a red fluor. The lower set of panels shows localization of mouse odorant receptor 28 (MOR28; green), a classical odorant receptor, and TAAR6 (red). Each stained patch in the images is the staining pattern of an individual olfactory neuron. The “merge” panels show the two other images superimposed. What do these data suggest about expression patterns of the TAARs?

b. A number of cell lines that produce neither classical odorant receptors nor TAARs have each been transfected with the gene encoding a different TAAR. The cells have also been cotransfected with a gene encoding secreted alkaline

phosphatase (SEAP) under control of a cAMP-responsive element. The cells are then exposed to various amines, as shown in the following figure, and SEAP activity in the medium is determined. The figure shows data for some representative TAARs (m = mouse, h = human). What do these data reveal about TAARs? What does the SEAP activity assay reveal about the signaling pathway utilized by chemoreception involving TAARs?

c. In a third set of studies, SEAP activity was measured in cells expressing mouse TAAR5 (mTAAR5) following exposure of the cells to diluted urine derived from two strains of mice or from humans, as indicated on the graphs below. Mice reach puberty at about one month of age. What do these data suggest may be a biological function for the TAAR5 neurons in mice? What additional studies would you conduct to support your hypothesis?

IMMUNOLOGY

Immunity is a state of protection against the harmful effects of exposure to pathogens. Host defense can take many different forms, and all successful pathogens have found ways to disarm the immune system or manipulate it to their own advantage. Host–pathogen interactions are therefore an evolutionary work in progress. This explains why we continue to be assaulted by pathogenic viruses, bacteria, and parasites. The prevalence of infectious diseases illustrates the imperfections of host defense. But killing its host is not necessarily advantageous to a pathogen because complete elimination of the host would immediately remove the reservoir in which the pathogen replicates or survives. An immune system that could produce perfect sterilizing immunity would yield a world without pathogens, an outcome clearly at variance with life as we know it. Rather, the co-evolution of pathogens and their hosts allows pathogens, which have relatively short generation times, to continue to evolve sophisticated countermeasures, against which the host must respond by adjusting, if not improving, its defenses. Sophisticated defense comes at a price: An immune system capable of dealing with a massively diverse collection of rapidly evolving pathogens may mount an attack on the host organism’s own cells and tissues, a phenomenon called *autoimmunity*.

In this chapter we deal mostly with the vertebrate immune system, with particular emphasis on those molecules, cell types, and pathways that uniquely distinguish the immune system from other types of cell and tissues. Host defense comprises three layers: (1) mechanical/chemical defenses, (2) innate immunity, and (3) adaptive immunity (Figure 24-1). Mechanical and chemical defenses operate continuously. Innate immune responses, which involve cells

and molecules present at all times, are rapidly activated (minutes to hours), but their ability to distinguish among many different pathogens is somewhat limited. In contrast, adaptive immune responses take several days to develop fully and are highly specific; that is, they can distinguish between closely related pathogens based on very small molecular differences in structure.

The manner in which **antigens**—any material that can evoke an immune response—are recognized and how these foreign materials are eliminated involve molecular and cell biological principles unique to the immune system. We begin this chapter with a brief sketch of the organization of the

▲ FIGURE 24-1 The three layers of vertebrate immune defenses. *Left:* Mechanical defenses consist of epithelia and skin. Chemical defenses include the low pH of the gastric environment and antibacterial enzymes in tear fluid. These barriers provide continuous protection against invaders. Pathogens must physically breach these defenses (1) to infect the host. *Middle:* Pathogens that have breached the mechanical and chemical defenses (2) are handled by cells and molecules of the innate immune system (blue), which includes phagocytic cells (neutrophils, dendritic cells, macrophages), natural killer (NK) cells, complement proteins, and certain interleukins (IL-1, IL-6). Innate defenses are activated within

minutes to hours of infection. *Right:* Pathogens that are not cleared by the innate immune system are dealt with by the adaptive immune system (3), in particular B and T lymphocytes. Full activation of adaptive immunity requires days. The products of an innate response may potentiate an ensuing adaptive response (4). Likewise, the products of an adaptive immune response, including antibodies (Y-shaped icons), may facilitate functioning of the innate immune system (5). Several cell types and secreted products straddle the fence between the innate and adaptive immune systems, and serve to connect these two layers of host defense.

mammalian immune system, introducing the essential players of innate and adaptive immunity and describing inflammation, a localized response to injury or infection that leads to the activation of immune-system cells and their recruitment to the affected site. In the next two sections, we discuss the structure and function of **antibody** (or immunoglobulin) molecules, which bind to specific molecular features on antigens, and how variability in antibody structure contributes to specific recognition of antigens. The enormous diversity of antigens that can be recognized by the immune system finds its explanation in unique rearrangements of the genetic material in B and T lymphocytes, commonly called **B cells** and **T cells**, which are the white blood cells that carry out antigen-specific recognition. These gene rearrangements not only control the specificity of antigen receptors on lymphocytes but also determine cell-fate decisions in the course of lymphocyte development.

Although the mechanisms that give rise to antigen-specific receptors on B and T cells are very similar, the manner in which these receptors recognize antigen is very different. The receptors on B cells can interact with intact antigens directly, but the receptors on T cells cannot. Instead, as described in Section 24.4, the receptors on T cells recognize cleaved (processed) forms of antigen, presented on the surface of target cells by glycoproteins encoded by the major histocompatibility complex (MHC). How MHC-encoded glycoproteins display these processed antigens is important for our understanding of how immune responses are initiated. MHC-encoded glycoproteins also help determine the developmental fate of T cells so that an organism's own cells and tissues (self antigens) normally do not evoke an immune response, whereas foreign antigens do. We conclude the chapter with an integrated view of the immune response to a pathogen, highlighting the collaboration between different immune-system cells that is required for an effective response.

24.1 Overview of Host Defenses

Because the immune system evolved to deal with pathogens, we begin our overview of host defenses by examining where typical pathogens are found and where they replicate. Then we introduce basic concepts of innate and adaptive immunity, including some of the key cellular and molecular players.

Pathogens Enter the Body Through Different Routes and Replicate at Different Sites

Pathogens affect all life forms capable of independent replication. Two general classes of pathogen, viruses and bacteria, have fundamentally different modes of propagation. With the exception of polymerases involved in copying genetic material, viruses generally lack the necessary machinery to synthesize their component parts and therefore are completely dependent on host cells for their propagation. In contrast, most bacteria are metabolically autonomous and do not rely on their host for replication, which allows them to be grown in the laboratory in the appropriate culture media. (An exception is those bacteria that can replicate only within a mammalian host cell.) Bacteria can cause disease because they possess virulence factors that act on the host's metabolism and physiology. Parasitic organisms also can cause disease. With increasingly complex life cycles such as those of the protozoa that cause sleeping sickness (trypanosomes) or malaria (*Plasmodium* species) (see Figure 1-4), the pathogen's countermeasures also become increasingly complex. Bacteria, protozoa, and fungi—especially those that can cause disease in animals—often are called microbes.

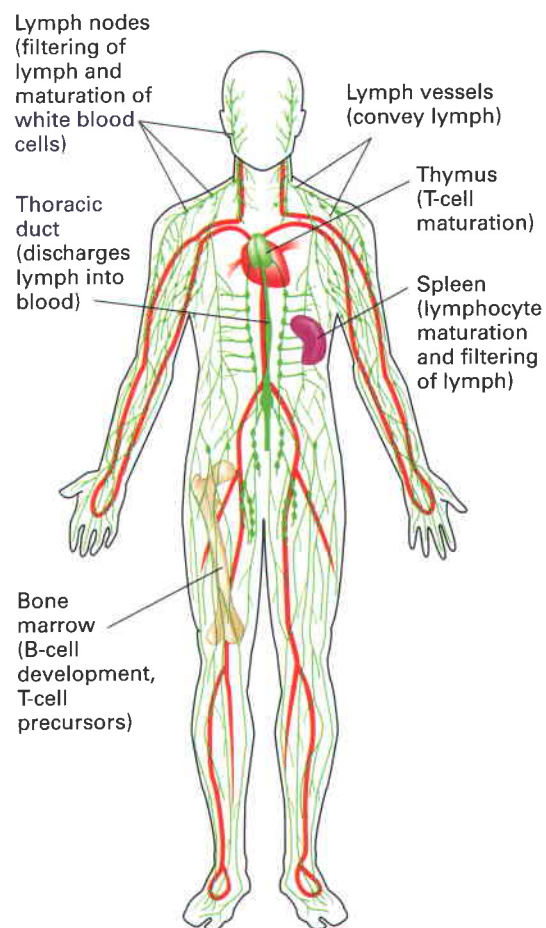

Exposure to pathogens occurs via different routes. The skin itself has a surface area of ≈ 20 sq. ft.; the epithelial surfaces that line the airways, gastrointestinal tract, and genital tract present an even more formidable surface area of ≈ 4000 sq. ft. All these surfaces are continuously exposed to viruses and bacteria in the environment. Foodborne pathogens and sexually transmitted agents target the epithelia to which they are exposed. The sneeze of a flu-infected individual releases millions of virus particles in aerosolized form, ready for inhalation by the next person to be infected. Rupture of the skin, even if only by minor abrasions, or of the epithelial barriers that protect the underlying tissues, provides an easy route of entry for pathogens, which then gain access to a rich source of nutrients (for bacteria) and to the cells required for their replication (viruses).

Replication of viruses is strictly confined to the cytoplasm or nucleus of host cells, where protein synthesis and replication of the viral genetic material occur. Viruses spread to other cells either as free virus particles (virions) or by cell-to-cell spread. Many bacteria can replicate in the intercellular space, but some are specialized to invade host cells and survive there. Such intracellular bacteria reside either in membrane-delimited vesicles through which they enter cells by endocytosis or phagocytosis or in the cytoplasm if they escape from these vesicles. An effective host defense system, therefore, needs to be capable of eliminating not only cell-free viruses and free-living bacteria but also cells that harbor these pathogens.

Leukocytes Circulate Throughout the Body and Take Up Residence in Tissues and Lymph Nodes

With the exception of erythrocytes, few cells in the course of their assigned function cover such distances as do the cells that provide immunity. The mammalian circulation serves as the necessary transport vehicle for erythrocytes, leukocytes, and platelets. Although erythrocytes never leave the circulation (their oxygen-carrying function does not require it), leukocytes (white blood cells) use the circulation exclusively for transport and may leave and re-enter the circulation in the course of their tasks.

The immune system is an interconnected system of vessels, organs, and cells, divided into primary and secondary lymphoid structures (Figure 24-2). *Primary lymphoid organs*—the sites at which **lymphocytes** (the subset of leukocytes that includes B and T cells) are generated and acquire their

▲ **FIGURE 24-2 The circulatory and lymphatic systems.** Positive arterial pressure exerted by the pumping heart is responsible for loss of liquid from the circulation (red) into the interstitial spaces of the tissues, so that all cells of the body have access to nutrients and can dispose of waste. This interstitial fluid, whose volume is roughly three times that of all blood in the circulation, is returned to the circulation in the form of lymph, which passes through specialized anatomical structures called lymph nodes. The primary lymphoid organs, where lymphocytes are generated, are the bone marrow (B cells, T-cell precursors) and the thymus (T cells). The initiation of an immune response involves the secondary lymphoid organs (lymph nodes, spleen).

functional properties—include the thymus, where T cells are generated, and the bone marrow, where B cells are generated. Adaptive immune responses, which require functionally competent lymphocytes are initiated in *secondary lymphoid organs* including lymph nodes and the spleen. All of the lymphoid organs are populated by cells of hematopoietic origin (see Figure 21-15), generated in the fetal liver and throughout life in the bone marrow. The total number of lymphocytes in a young adult male is estimated to be 500×10^9 , roughly 15 percent of which are found in the spleen, 40 percent in the other secondary lymphoid organs (tonsils, lymph nodes), 10 percent in the thymus, and 10 percent in the bone marrow; the remainder are circulating in the bloodstream.

Leukocytes must leave the bloodstream and enter tissues to perform their functions. Vertebrate blood vessels allow the escape of fluid from the circulation, driven by the positive arterial pressure exerted by the pumping heart. This fluid contains not only nutrients but also proteins that carry out defensive functions. To maintain homeostasis, the fluid that leaves the circulation must ultimately return and does so in the form of *lymph*, via lymphatic vessels. The total volume of lymph is up

to three times the total blood volume. At their most distal ends, lymphatic vessels are open to collect the interstitial fluid that bathes the cells in tissues. The lymphatic vessels merge into larger collecting vessels, which deliver lymph to *lymph nodes*. A lymph node consists of a capsule, organized into areas that are defined by the cell types that inhabit them. Blood vessels entering a lymph node deliver B and T cells to it. The lymph that arrives in a lymph node carries cells that have encountered (“sampled”) antigen, as well as soluble antigens, from the tissue drained by that particular afferent lymphatic vessel. In the lymph node, the cells and molecules required for the adaptive immune response interact, respond to the newly acquired antigenic information, and then execute the necessary effector functions to rid the body of the pathogen (Figure 24-3).

Lymph nodes can be thought of as filters in which antigenic information gathered from distal sites throughout the body is collected and displayed to the immune system in a form suitable to evoke an appropriate response. All the relevant steps that lead to lymphocyte activation take place in lymphoid organs. Cells that have received proper instructions to become functionally active leave the lymph node via efferent

▲ FIGURE 24-3 Initiation of the adaptive immune response in lymph nodes. Recognition of antigen by B and T cells (lymphocytes) located in lymph nodes initiates an adaptive immune response. Lymphocytes leave the circulation and take up residence in lymph nodes (1). Lymph carries antigen in two forms—soluble antigen and antigen-laden dendritic cells; both are delivered to lymph nodes via afferent lymphatics (2, 3). Soluble antigen is recognized by B cells

(4), and antigen-laden dendritic cells present antigen to T cells (5). Productive interactions between T and B cells (6) allow B cells to move into follicles and differentiate into plasma cells, which produce large amounts of secreted immunoglobulins (antibodies). Efferent lymphatic vessels return lymph from the lymph node to the circulation.

lymphatic vessels that ultimately drain into the circulation. Such activated cells recirculate through the bloodstream and—now ready for action—may reach a location where they again leave the circulation, move into tissues, and seek out pathogenic invaders or destroy virus-infected cells.

The exit of lymphocytes and other leukocytes from the circulation, recruitment of these cells to sites of infection, processing of antigenic information, and return of immune-system cells to the circulation are all carefully regulated processes that involve specific cell-adhesion events, chemotactic cues, and the traversal of endothelial barriers, as we discuss later.

Mechanical and Chemical Boundaries Form a First Layer of Defense Against Pathogens

As noted already, mechanical and chemical defenses form the first line of host defense against pathogens (see Figure 24-1). Mechanical defenses include the skin, epithelia, and arthropod exoskeleton, which are barriers that can be breached only by mechanical damage or through specific chemo-enzymatic attack. Chemical defenses include not only the low pH found in gastric secretions but also enzymes such as *lysozyme*, found in tear fluid, which can attack microbes directly.

The importance of mechanical defenses, which operate continuously, are immediately obvious in the case of burn victims: When the integrity of the epidermis and dermis is compromised, the rich source of nutrients in the underlying tissues is exposed, and airborne bacteria or otherwise harmless bacteria found on the skin can multiply unchecked, ultimately overwhelming the host. Viruses and bacteria have also evolved strategies to breach the integrity of these physical barriers. Enveloped viruses such as HIV, rabies virus, and influenza virus possess membrane proteins endowed with fusogenic properties. Following adhesion of a virion to the surface of the cell to be infected, direct fusion of the viral envelope with the host cell's membrane results in delivery of the viral genetic material into the host cytoplasm, where it is now available for transcription, translation, and replication (see Figures 4-47 and 4-49). Certain pathogenic bacteria (e.g., *S. aureus*) secrete collagenases that compromise the integrity of connective tissue and so facilitate entry of the bacteria.

Innate Immunity Provides a Second Line of Defense After Mechanical and Chemical Barriers Are Crossed

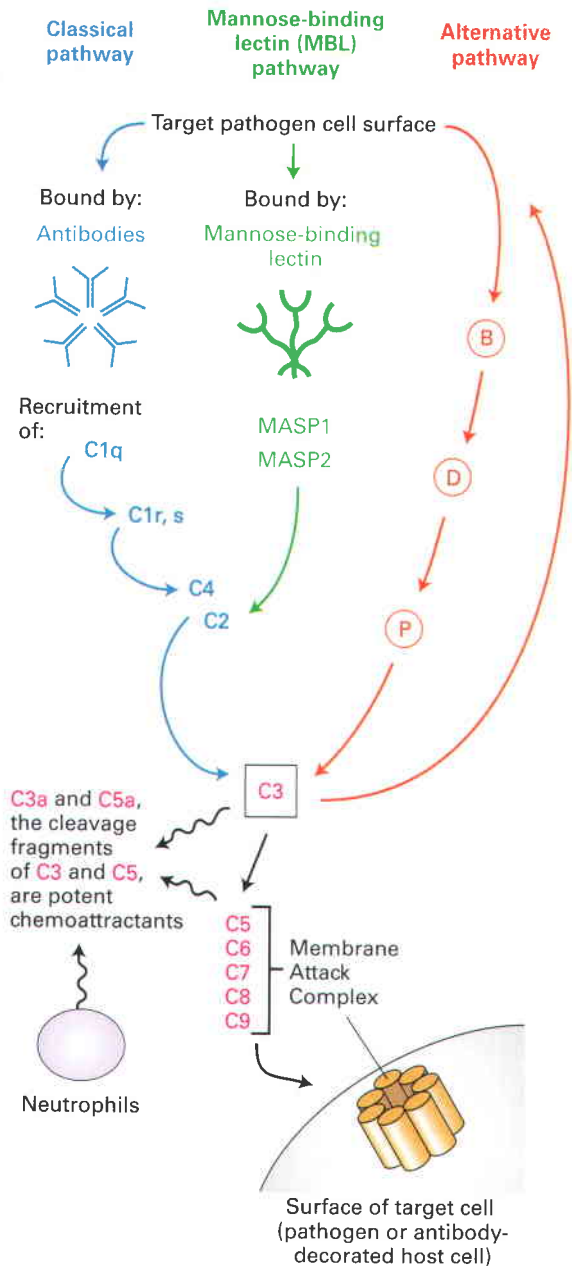

The innate immune system is activated once the mechanical and chemical defenses have failed, and the presence of an invader is sensed (see Figure 24-1). The innate immune system comprises cells and molecules that are immediately available for responding to pathogens. **Phagocytes**, cells that ingest and destroy pathogens, are widespread throughout tissues and epithelia and can be recruited to sites of infection. Several soluble proteins present constitutively in the blood, or produced in response to infection or inflammation, also contribute to innate defense. Animals that lack an adaptive immune system, such as insects, rely exclusively on innate defenses to combat infections.

Phagocytes and Antigen-Presenting Cells The innate immune system includes macrophages, neutrophils, and dendritic cells. All of these cells are phagocytic and come equipped with **Toll-like receptors (TLRs)**. Members of this family of cell-surface proteins detect broad patterns of pathogen-specific markers and thus are key sensors for detecting the presence of viral or bacterial invaders. Engagement of Toll-like receptors is important in eliciting effector molecules, including antimicrobial peptides. **Dendritic cells** and **macrophages** whose Toll-like receptors have detected pathogens also function as **antigen-presenting cells (APCs)** by displaying processed foreign materials to antigen-specific T cells. The structure and function of Toll-like receptors and their role in activating dendritic cells are described in detail in Section 24.6.

Complement System Another important component of the innate immune system is **complement**, a collection of constitutive serum proteins that can bind directly to microbial or fungal surfaces. This binding activates a proteolytic cascade that culminates in formation of pore-forming proteins constituting the *membrane attack complex*, which is capable of permeabilizing the pathogen's protective membrane (Figure 24-4). The complement cascade is conceptually similar to the blood-clotting cascade, with amplification of the reaction at each successive stage of activation. At least three distinct pathways can activate complement. The *classical pathway* requires the presence of antibodies produced in the course of an adaptive response and bound to the surface of the microbe. Many microbial surfaces directly activate complement via the *alternative pathway*. Finally, pathogens that contain mannose-rich cell walls activate complement through the *mannose-binding lectin pathway*. The bound lectin then triggers activation of two mannose-binding lectin-associated proteases, MASP-1 and MASP-2, which allow activation of the downstream components of the complement cascade.

In the course of complement activation, the C3 and C4 complement proteins occupy a special role. These abundant serum proteins are synthesized as precursors that contain an internal, strained thioester linkage between a cysteine and a glutamate residue in close proximity. This thioester linkage becomes highly reactive upon proteolytic activation of C3 and C4 by their respective upstream partners. The activated thioester bond can react with primary amines or hydroxyls in close proximity, yielding a covalent bond linking C3 or C4 with a protein or carbohydrate close-by. If no such reactants are available, the thioester bond is simply hydrolyzed. This mode of action ensures that C3 and C4 fragments will be covalently deposited only on antigen-antibody complexes in close proximity.

Regardless of the pathway of complement activation engaged, activated C3 unleashes the terminal components of the complement cascade, C5 through C9, culminating in formation of the membrane attack complex, which inserts itself into most biological membranes and renders them permeable. The resulting loss of electrolytes and small solutes leads to lysis and death of the target cell. Whenever

▲ FIGURE 24-4 Three pathways of complement activation. The classical pathway involves the formation of antibody–antigen complexes, which recruit the complement component C1q, leading to activation of C1r and C1s. This complex, in turn activates C4 and C2, which then convert C3 to its active form. In the mannose-binding lectin pathway, mannose-rich structures found on the surface of many pathogens are recognized by mannose-binding lectin, an interaction that results in activation of two serine proteases, MASP-1 and MASP-2. The alternative pathway requires deposition of a special form of the serum protein C3, a major complement component, onto a microbial surface. Subsequent activation of C3 involves factors B, D and P, found in serum. Each of the activation pathways is organized as a cascade of proteases in which the downstream component is itself a protease. Amplification of activity occurs with each successive step. All three pathways converge on C3, which triggers formation of the membrane attack complex, leading to destruction of target cells. The small fragments of C3 and C5 generated in the course of complement activation attract neutrophils, phagocytic cells that can kill bacteria at short range or upon ingestion.

complement is activated, the membrane attack complex is formed and results in death of the cell onto which the complex is deposited. The direct microbicidal effect of a fully activated complement cascade is an important protective function.

All three complement activation pathways also generate the C3a and 5a cleavage fragments, which bind to G protein–coupled receptors and function as chemoattractants for neutrophils and other cells involved in inflammation (see below). All three pathways also result in the covalent decoration of the structures targeted by complement activation with fragments of C3. Phagocytic cells make use of these C3-derived tags to recognize, ingest, and destroy the decorated particles, a process termed *opsonization*.

Natural Killer (NK) Cells In addition to bacterial invaders, the innate immune system also defends against viruses. When the presence of a virus-infected cell is detected, yet other cell types of the innate immune system become active, seek out the virus-infected targets, and kill them. For instance, many virus-infected cells produce type I **interferons**, which are good at activating **natural killer (NK) cells**. Activated NK cells not only afford direct protection by eliminating the factory of new virus particles, but they also secrete interferon γ (IFN- γ), which is essential for orchestrating many aspects of anti-viral defenses (Figure 24-5). Recognition by NK cells involves several classes of receptors, capable of delivering either stimulatory (promoting cell killing) or inhibitory signals. The interferons are classified as **cytokines**, small, secreted proteins that help regulate immune responses in a variety of ways. We will encounter

▲ FIGURE 24-5 Natural killer cells. Natural killer (NK) cells are an important source of the cytokine interferon γ (IFN- γ) and can kill virus-infected and cancerous cells by means of perforins. These pore-forming proteins allow access of serine proteases called granzymes to the cytoplasm of the cell about to be killed. Granzymes also can initiate apoptosis through activation of caspases (Chapter 21).

other cytokines and discuss some of their receptors as the chapter progresses.

Inflammation Is a Complex Response to Injury That Encompasses Both Innate and Adaptive Immunity

When a vascularized tissue is injured, the stereotypical response that follows is **inflammation**. Damage may be a simple paper cut or result from infection with a pathogen. Inflammation, or the inflammatory response, is characterized by four classical signs: *redness*, *swelling*, *heat*, and *pain*. These signs are caused by increased leakiness of blood vessels (vasodilation), the attraction of cells to the site of damage, and the production of soluble mediators responsible for the sensation of heat and pain. Inflammation has immediate protective value through the activation of the cell types and soluble products that together mount the innate immune response. Further, inflammation creates a local environment conducive to the initiation of the adaptive immune response. However, if not properly controlled, inflammation can also be a major cause of tissue damage.

Figure 24-6 depicts the key players in the inflammatory response to bacterial pathogens and the subsequent initiation of an adaptive immune response. Tissue-resident dendritic cells sense the presence of pathogens via their Toll-like receptors (TLRs) and respond to them by releasing soluble mediators such as cytokines and **chemokines**; the latter act as chemoattractants for immune-system cells. Neutrophils, a second important cell type in the inflammatory response, leave the circulation and migrate to wherever tissue injury or infection has occurred in response to various soluble mediators produced upon tissue damage. **Neutrophils**, which constitute almost half of all circulating leukocytes, are phagocytic, directly ingesting and destroying pathogenic bacteria. They also can interact with a wide variety of pathogen-derived macromolecules via their Toll-like receptors. Activation of these receptors allows neutrophils to produce cytokines and chemokines; the latter can attract more leukocytes—neutrophils, macrophages, and ultimately lymphocytes (T and B cells)—to the area. Activated neutrophils can release bacteria-destroying enzymes (e.g., lysozyme and proteases) as well as small peptides with microbicidal activity, collectively called *defensins*. Activated neutrophils also turn on the enzymes that generate superoxide anion and other reactive oxygen species (see Chapter 12, p. 502), which can kill microbes at short range. Another cell type contributing to the inflammatory response is tissue-resident *mast cells*. When activated by a variety of physical or chemical stimuli, mast cells release histamine, a mediator that increases vascular permeability and thereby facilitates access to the site of plasma proteins (e.g., complement) that can act against the invading pathogen.

A very important early response to infection or injury is activation of a variety of plasma proteases, including the proteins of the complement cascade discussed above (see Figure 24-4). The peptides produced during activation of these proteases possess chemoattractant activity, responsible for attracting neutrophils to the site of tissue damage. They further induce production of proinflammatory cytokines such as

▲ **FIGURE 24-6 Interplay of innate and adaptive immune responses against a bacterial pathogen.** Once a bacterium breaches the host's mechanical and chemical defenses, the bacterium is exposed to components of the complement cascade, as well as to cells that confer immediate protection, such as neutrophils (1). Various inflammatory mediators induced by tissue damage contribute to a localized inflammatory response. Local destruction of the bacterium results in the release of bacterial antigens, which are delivered via the afferent lymphatics to the draining lymph node (2). Dendritic cells acquire antigen at the site of infection, become migratory in response to microbial products, and move to the lymph node, where they activate T cells (3). In the lymph node, antigen-stimulated T cells proliferate and acquire effector functions, including the ability to help B cells (4), some of which may move to the bone marrow and complete their differentiation into plasma cells there (5). In later stages of the immune response, activated T cells provide additional assistance to antigen-experienced B cells to yield plasma cells that secrete antigen-specific antibodies at a high rate (step 6). Antibodies produced as a consequence of the initial exposure to bacteria act in synergy with complement to eliminate the infection (7), should it persist, or afford rapid protection in the case of re-exposure to the same pathogen.

interleukin 1 and 6 (IL-1 and IL-6). The recruitment of neutrophils also depends on an increase in vascular permeability, controlled in part by lipid mediators (e.g., prostaglandins and leukotrienes) that are derived from phospholipids and fatty

acids. All of these events occur rapidly, starting within minutes of injury. A failure to resolve the cause of this immediate response may result in chronic inflammation, in which cells of the adaptive immune system play an important role.

When the pathogen burden at the site of tissue damage is high, it may exceed the capacity of innate defense mechanisms to deal with them. Moreover, some pathogens have acquired, in the course of evolution, tools to disable or bypass innate immune defenses. In such situations, the adaptive immune response is required to control the infection. This adaptive response depends on specialized cells that straddle the interface between adaptive and innate immunity, including antigen-presenting cells such as macrophages and dendritic cells, which are capable of acquiring intact pathogens and of killing them upon ingestion. These antigen-presenting cells, in particular dendritic cells, can initiate an adaptive immune response by delivering newly acquired pathogen-derived antigens to secondary lymphoid organs (see Figure 24-6).

Adaptive Immunity, the Third Line of Defense, Exhibits Specificity

Lymphocytes bearing antigen-specific receptors are the key cells responsible for adaptive immunity. An early indication of the specific nature of adaptive responses came with the discovery of antibodies, key effector molecules of adaptive immunity, by Emil von Behring and Shibasaburo Kitasato in 1905. They observed that when serum (the straw colored liquid that separates from cellular debris upon completion of the blood clotting process) from guinea pigs immunized with a sublethal dose of the deadly diphtheria toxin was transferred to animals never before exposed to the bacterium, the recipient animals were protected against a lethal dose of the same bacterium, which kills its host by production of a toxin (Figure 24-7). Transfer of serum from animals never exposed to diphtheria toxin failed to protect, and protection was limited to the microbe used as the source of toxin with which the animal that

Podcast: The Discovery of Antibodies 

▲ EXPERIMENTAL FIGURE 24-7 The existence of antibody in serum from infected animals was demonstrated by von Behring and Kitasato. Exposure of animals to a sublethal dose of diphtheria toxin (or the bacteria that produce it) elicits in their serum a substance that protects against a subsequent challenge with a lethal dose of the toxin (or the bacteria that produce it). The protective effect of this serum substance can be transferred from an animal that has been exposed to the pathogen to a naive (nonexposed) animal. When the serum recipient is subsequently

exposed to a lethal dose of the bacteria, the animal survives. This effect is specific for the pathogen used to elicit the response. Serum thus contains a transferable substance (antibody) that protects against the harmful effects of a virulent pathogen. Serum harvested from these animals, said to be immune, displays bactericidal activity in vitro. Heating of immune serum destroys its bactericidal activity. Addition of fresh nonheated serum from a naive animal restores the bactericidal activity of heated immune serum. Serum thus contains another substance that complements the activity of antibodies.

MEDIA CONNECTIONS

served as the serum donor was immunized. This experiment demonstrates *specificity*—that is, the ability to distinguish between two closely related substances of the same class. Such specificity is a hallmark of the adaptive immune system. Even proteins that differ by a single amino acid may be distinguished by immunological means.

From these experiments, von Behring inferred the existence of corpuscles (“Antikörper”), or antibodies, as the factor responsible for protection. The antibody-containing (immune) sera not only afforded protection *in vivo*, they also killed microbes in the test tube. Heating the immune sera to 56° C destroyed this killing activity, but it was restored by the addition of unheated fresh serum from naive animals (i.e., animals never exposed to the microbe). This finding suggested that a second factor, now called complement, acts in synergy with antibodies to kill bacteria. We now know that von Behring’s antibodies are serum proteins referred to as **immunoglobulins** and that complement is actually a series of proteases (see Figure 24-4). Immunoglobulins can neutralize not only bacterial toxins, but also harmful agents such as viruses, by directly binding to them in a manner that prevents the virus from attaching itself to host cells. In the same vein, antibodies raised against snake venoms can be administered to the victims of snake bites to protect them from intoxication: The anti-snake venom antibodies bind to the venom, keep it from binding to its targets in the host, and in so doing neutralize it. Antibodies can thus have immediate protective effects.

KEY CONCEPTS OF SECTION 24.1

Overview of Host Defenses

- Mechanical and chemical defenses provide protection against most pathogens. This protection is immediate and continuous, yet possesses little specificity. Innate and adaptive immunity provide defenses against pathogens that breach the body’s mechanical/chemical boundaries (see Figure 24-1).
- The circulatory and lymphatic systems distribute the molecular and cellular players in innate and adaptive immunity throughout the body (see Figure 24-2).
- Innate immunity is mediated by the complement system (see Figure 24-4) and several types of leukocytes, the most important of which are neutrophils and other phagocytic cells such as macrophages and dendritic cells. The cells and molecules of innate immunity are deployed rapidly (minutes to hours). Molecular patterns diagnostic of the presence of pathogens can be recognized by Toll-like receptors, but the specificity of recognition is modest.
- Adaptive immunity is mediated by T and B lymphocytes. These cells require days for full activation and deployment, but they can distinguish between closely related antigens. This specificity of antigen recognition is the key distinguishing feature of adaptive immunity.
- Innate and adaptive immunity act in a mutually synergistic fashion. Inflammation, an early response to tissue injury or infection, involves a series of events that combines elements of innate and adaptive immunity (see Figure 24-6).

24.2 Immunoglobulins: Structure and Function

Immunoglobulins, produced by B cells, are the best-understood molecules that confer adaptive immunity. In this section we describe the overall structural organization of immunoglobulins, their structural diversity, and how they bind to antigens.

Immunoglobulins Have a Conserved Structure Consisting of Heavy and Light Chains

Like complement, immunoglobulins are abundant serum proteins that can be classified in terms of their structural and functional properties. Fractionation of antisera, based on their functional activity (e.g., killing of microbes, binding of antigen), led to the identification of the immunoglobulins as the class of serum proteins responsible for antibody activity. Immunoglobulins are composed of two identical *heavy (H) chains*, covalently attached to two identical *light (L) chains* (Figure 24-8).

▲ **FIGURE 24-8** The basic structure of an immunoglobulin molecule. Antibodies are serum proteins also known as immunoglobulins. They are two-fold symmetrical structures composed of two identical heavy chains and two identical light chains. Fragmentation of antibodies with proteases yields fragments that retain antigen-binding capacity. The protease papain yields monovalent F(ab) fragments, and the protease pepsin yields bivalent F(ab')₂ fragments. The Fc fragment is unable to bind antigen, but this portion of the intact molecule has other functional properties.

◀ **FIGURE 24-9 Immunoglobulin isotypes.**

The different classes of immunoglobulins, called isotypes, may be distinguished biochemically and by immunological techniques. In mouse and humans there are two light-chain isotypes (κ and λ) and five heavy-chain isotypes (μ , δ , γ , ϵ , α). (a) Based on the identity of the heavy chain, each isotype defines a class of immunoglobulin. IgG, IgE, and IgD (not shown) are monomers with generally similar overall structures. IgM and IgA are unusual because they can occur in serum as pentamers and dimers, respectively, accompanied by an accessory subunit, the J chain, in covalent disulfide linkage. (b) This volume-rendered depiction of the IgM pentamer highlights the modular design of a typical immunoglobulin with each barrel representing an individual Ig domain. Each loop in the diagrams shown in part (a) also represent an Ig domain. Different isotypes have different functions. See Figure 24-12 for definitions of abbreviations.

The typical immunoglobulin therefore has a two-fold symmetrical structure, described as H_2L_2 . An exception to this basic H_2L_2 architecture occurs in the camelids (camels, llamas, vicunas). These animals can make some immunoglobulins that are heavy-chain dimers (H_2) and lack light chains.

A biochemical approach was used to answer the question of how antibodies manage to distinguish between related antigens. Proteolytic enzymes were used to fragment immunoglobulins, which are rather large proteins, to identify the regions directly involved in antigen binding (see Figure 24-8). The protease papain yields monovalent fragments,

called $F(ab)$, that can bind a single antigen molecule, whereas the protease pepsin yields bivalent fragments, referred to as $F(ab')_2$ (F = fragment; ab = antibody). These enzymes are commonly used to convert intact immunoglobulin molecules into monovalent or bivalent reagents. Although $F(ab)$ fragments are incapable of cross-linking, $F(ab')_2$ fragments can do so, a property frequently used to cross-link and so activate surface receptors. The portion released upon papain digestion and incapable of antigen binding is called F_c , because of its ease of crystallization (F = fragment; c = crystallizable). This biochemical approach using proteases was followed by peptide mapping and sequencing strategies to determine the primary structure of the immunoglobulins.

Multiple Immunoglobulin Isotypes Exist, Each with Different Functions

Based on their distinct biochemical properties, immunoglobulins are divided into different classes, or *isotypes*. There are two light-chain isotypes, κ and λ . The heavy chains show more variation: In mammals, the major heavy-chain isotypes are μ , δ , γ , α , and ϵ . These heavy chains can associate with either κ or λ light chains. Depending on the vertebrate species, further subdivisions occur for the α and γ chains, and fish possess an isotype not found in mammals. The fully assembled immunoglobulin (Ig) derives its name from the heavy chain: μ chains yield IgM; α chains, IgA; γ chains, IgG, δ chains, IgD; and ϵ chains, IgE. The general structures of the major Ig isotypes are depicted in Figure 24-9. By means of their unique structural features, each of the different Ig isotypes carries out specialized functions.

The IgM molecule is secreted as a pentamer, stabilized by disulfide bonds and an additional chain, the J chain. In its pentameric form, IgM possesses 10 identical antigen-binding sites, which allow high-avidity interactions with surfaces that display the corresponding (cognate) antigen. Upon deposition of IgM onto a surface that carries the antigen, the pentameric IgM molecule assumes a conformation highly conducive to activation of the complement cascade, an effective means of damaging the membrane onto which IgM is adsorbed and onto which complement proteins are deposited as a consequence.

The IgA molecule also interacts with the J chain, forming a dimeric structure. Dimeric IgA can bind to the polymeric IgA receptor on the basolateral side of epithelial cells, where its engagement results in receptor-mediated endocytosis. Subsequently, the IgA receptor is cleaved and dimeric IgA with the proteolytic receptor fragment (secretory piece) still attached is released from the apical side of the epithelial cell. This process, called **transcytosis**, is an effective means of delivering immunoglobulins from the basolateral side of an epithelium to the apical side (Figure 24-10a). Tear fluid and other secretions are rich in IgA and so provide protection against environmental pathogens.

The IgG isotype is important for neutralization of virus particles. This isotype also helps prepare particulate antigens for acquisition by cells equipped with receptors specific for the Fc portion of IgG molecules (see below).

▲ **FIGURE 24-10 Transcytosis of IgA and IgG.** (a) IgA, found in secretions of the different mucosae, requires transport across the epithelium. IgA binds to the polymeric IgA receptor and is endocytosed. After being transported across the epithelial monolayer, a portion of the receptor is cleaved, and the IgA is released at the apical side together with a portion of the receptor, the secretory piece. (b) Suckling rodents acquire Ig from mother's milk. The newborn possesses at the apical surface of its intestinal epithelium the neonatal Fc receptor (FcRn), whose structure resembles that of class I MHC molecules (see Figure 24-21). After this receptor binds to the Fc portion of IgG, transcytosis moves the acquired IgG to the basolateral side of the epithelium. In humans, the syncytial trophoblast in the placenta expresses FcRn and so mediates acquisition of IgG from the maternal circulation and delivery to the fetus (transplacental transport).

The immune system of the newborn is immature, and in rodents protective antibodies are transferred from the mother to the fetus via the mother's milk. The receptor responsible for capturing maternal IgG is the neonatal Fc receptor, which

is present on intestinal epithelial cells in rodents. By transcytosis, IgG captured on the luminal side of the newborn's intestinal tract is delivered across the gut epithelium and so makes maternal antibodies in the milk available for passive protection of the infant rodent (Figure 24-10b). In humans, the Fc receptor is found on fetal cells that contact the maternal circulation. Transcytosis of IgG antibodies from the maternal circulation across the placenta delivers maternal antibodies to the fetus. These maternal antibodies will protect the newborn until its own immune system is sufficiently mature to produce antibodies under its own steam.

Each B Cell Produces a Unique, Clonally Distributed Immunoglobulin

The *clonal selection theory* stipulates that each lymphocyte carries an antigen-binding receptor of unique specificity. When a lymphocyte encounters the antigen for which it is specific, clonal expansion (or multiplication) occurs and so allows an amplification of the response, culminating in clearing of the antigen (Figure 24-11).

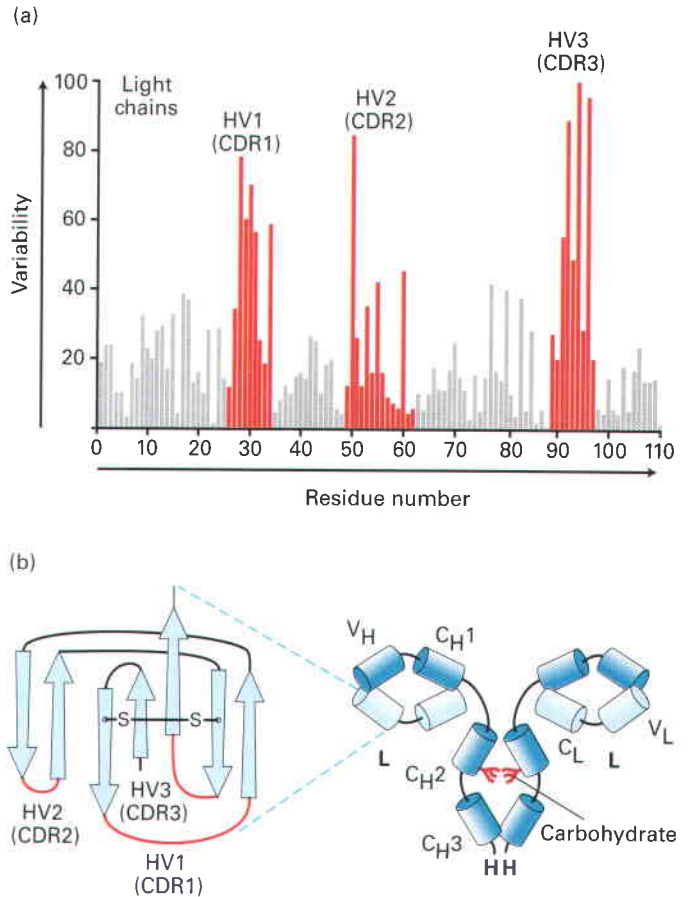

B-cell tumors, which represent malignant clonal expansions of individual lymphocytes, enabled the first molecular analysis of the processes that underlie the generation of antibody diversity. A key observation was that tumors derived from lymphocytes may produce large quantities of secreted immunoglobulins. Some of the light chains of the immunoglobulins are secreted in the urine of tumor-bearing patients. These light chains, called *Bence-Jones proteins* after

▲ **FIGURE 24-11 Clonal selection.** The clonal selection theory proposes the existence of a large set of lymphocytes, each equipped with its own unique antigen-specific receptor (indicated by different colors). The antigen that shows a fit with the receptor carried by a particular lymphocyte allows that lymphocyte to expand clonally. From a modest number of antigen-specific cells, a large number of cells of the desired specificity (and large amounts of their secreted outputs) may be generated.

their discoverers, are readily purified and afforded the first target for a protein chemical analysis.

Two key observations emerged from this work: (1) no two tumors produced light chains of the identical biochemical properties, suggesting that they were all unique in sequence and (2) the differences in amino acid sequence that distinguish one light chain from another are not randomly distributed but occur clustered in a domain referred to as the *variable region of the light chain*, or V_L . This domain comprises the N-terminal

▲ **FIGURE 24-12 Hypervariable regions and the immunoglobulin fold.** (a) Variation in amino acid variability with residue position in Ig light chains. The percentage of variable-region sequences with variant amino acids is plotted for each position in the sequence. Positions for which many different amino acid side chains are present in the data set are assigned a high variability index; those that are invariant among the sequences compared are assigned a value of 0. This analysis reveals three regions of increased variability, hypervariability (HV) regions 1, 2, and 3; these are also called complementarity-determining regions (CDRs). (b) Volume-rendered depiction of $F(ab')_2$ fragment (*right*) and ribbon diagram of a typical Ig light-chain variable domain (V_L) with the positions of the hypervariable regions indicated in red (*left*). The hypervariable regions are found in the loops that connect the β strands and make contact with antigen. The β strands (rendered as arrows) make up two β sheets and constitute the framework region. Note that each variable and constant domain has a characteristic three-dimensional structure, called the immunoglobulin fold. L = light chain; H = heavy chain; V_H = heavy-chain variable domain; V_L = light-chain variable domain; C_{H1} , C_{H2} , C_{H3} = heavy-chain constant domains; C_L = light-chain constant domain.

110 amino acids or so. The remainder of the sequence is identical for the different light chains (provided they derive from the identical isotype, κ or λ) and is therefore referred to as the *constant region*, or C_L . From the serum of tumor-bearing individuals, immunoglobulins unique to that individual patient subsequently were purified. Sequencing of the heavy chains from these preparations revealed that the variable residues that distinguish one heavy chain from another were again concentrated in a well-demarcated domain, referred to as the *variable region of the heavy chain*, or V_H .

An alignment of sequences obtained from different homogeneous light-chain preparations showed a non-random pattern of regions of variability, revealing three *hypervariable regions*—HV1, HV2, and HV3—which are sandwiched between what are called framework regions (Figure 24-12a). (Similar alignments for the immunoglobulin heavy-chain sequences also yield hypervariable regions.) In the properly folded three-dimensional structure of immunoglobulins, these hypervariable regions are in close proximity (Figure 24-12b) and make contact with antigen. Thus that portion of an Ig molecule containing the hypervariable regions constitutes the antigen-binding site. For this reason, hypervariable regions are also referred to as *complementarity-determining regions* (CDRs). The difficulty of encoding in the germ line all of the information necessary to generate this enormously diverse antibody repertoire led to suggestions of unique genetic mechanisms to account for this diversity.

Immunoglobulin Domains Have a Characteristic Fold Composed of Two β Sheets Stabilized by a Disulfide Bond

Both the variable and constant domains of immunoglobulins fold into a compact three-dimensional structure composed

exclusively of β sheets (see Figure 24-12b). A typical Ig domain contains two β sheets (one with three strands and one with four strands) held together by a disulfide bond. The residues that point inwards are mostly hydrophobic and help stabilize this sandwich structure. Solvent-exposed residues show a greater frequency of polar and charged side chains. The spacing of the cysteine residues that make up the disulfide bond and a small number of strongly conserved residues characterize this evolutionarily ancient structural motif, termed the **immunoglobulin fold**. The basic immunoglobulin fold is found in numerous eukaryotic proteins that are not directly involved in antigen-specific recognition, including the Ig superfamily of cell-adhesion molecules, or IgCAMs (Chapter 19).

The Three-Dimensional Structure of Antibody Molecules Accounts for Their Exquisite Specificity

The three-dimensional structure of immunoglobulins has been solved and the details of how an antibody interacts with an antigen are known at atomic resolution (Figure 24-13; see also Figure 3-19b). The contact area between an antibody and a protein antigen is on the order of $20 \times 30 \text{ \AA}$ and involves mostly interactions that require perfect complementarity. Hydrogen bonds and van der Waals interactions make important contributions to antigen-antibody binding. (For more discussion of the role of molecular complementarity in protein binding and function, see Chapter 2, p. 39.) Antibodies can be elicited not only against proteins, but also against modifications carried by some proteins (e.g., attached oligosaccharide chains or phosphate groups) or even small organic molecules that do not occur in nature. For reasons to be described in Section 24.4, the production of

▲ **FIGURE 24-13 Immunoglobulin structure.** This model shows the three-dimensional structure of an immunoglobulin complexed with

hen egg-white lysozyme (a protein antigen) as determined by x-ray crystallography. [Based on E. A. Padlan et al., 1989 *PNAS* **86**: 5938.]

antibodies specific for small nonprotein antigens requires conjugation of the antigen to carrier proteins, but the antibodies themselves can recognize these smaller antigens as such. The smaller the antigen, often the deeper it lies buried in the antigen-binding site of the antibody. The hypervariable regions of the heavy and light chains make the most extensive contacts with the antigen to which the antibody binds, with the third hypervariable regions making particularly significant contributions.

The region on an antigen where it makes contact with the corresponding antibody is called an **epitope**. A protein antigen usually contains multiple epitopes, which often are exposed loops or surfaces on the protein and thus accessible to antibody molecules. Each homogeneous antibody preparation, derived from a clonal population of B cells, recognizes a single molecularly defined epitope on the corresponding antigen.

In order to solve the structure of an antibody complexed to its cognate epitope on an antigen, it is important to have a source of homogeneous immunoglobulin and the antigen in pure form. Homogeneous immunoglobulins can be obtained from B-cell tumors (malignant monoclonal expansions of immunoglobulin-secreting B cells), but in that case the antigen for which the antibody is specific is not known. The breakthrough essential for generating homogeneous antibody preparations suitable for structural analysis was the development of techniques to obtain **monoclonal antibody** produced by **hybridomas** by use of a special selection medium (see Chapter 9, pp. 400–402).

An Immunoglobulin's Constant Region Determines Its Functional Properties

Antibodies recognize antigen via their variable regions, but their constant regions determine many of the functional properties of antibodies. An important functional property of antibodies is their neutralizing capacity. By binding to epitopes on the surface of virus particles or bacteria, antibodies may block a productive interaction between a pathogen and receptors on host cells, thereby inhibiting (neutralizing) infection.

Antibodies attached to a virus or microbial surface can be recognized directly by cells that express receptors specific for the Fc portion of immunoglobulins. These *Fc receptors* (FcRs), which are specific for individual classes and subclasses of immunoglobulins, display considerable structural and functional heterogeneity. By means of FcR-dependent events, specialized phagocytic cells such as dendritic cells and macrophages can engage antibody-decorated particles, then ingest and destroy them in the process of opsonization. FcR-dependent events also allow some immune-system cells (e.g., monocytes and natural killer cells) to directly engage target cells that display viral or other antigens to which antibodies are attached. This engagement may induce the immune-system cells to release toxic small molecules (e.g., oxygen radicals) or the contents of cytotoxic granules, including perforins and granzymes. These proteins can attach themselves to the surface of the engaged target cell, inflict

membrane damage, and so kill the target (see Figure 24-5). This process, called *antibody-dependent cell-mediated cytotoxicity*, illustrates how cells of the innate immune system interact with, and benefit from, the products of the adaptive immune response.

Depending on the immunoglobulin isotype, antigen-antibody (immune) complexes can initiate the classical pathway of complement activation (see Figure 24-4). IgM and IgG3 are particularly good at complement activation, but all IgG classes can in principle activate complement, whereas IgA and IgE are unable to do so.

KEY CONCEPTS OF SECTION 24.2

Immunoglobulins: Structure and Function

- Most immunoglobulins (antibodies) are composed of two identical heavy (H) chains and two light (L) chains, with each chain containing a variable (V) region and constant (C) region. Proteolytic fragmentation yields monovalent F(ab) and bivalent F(ab')₂ fragments, which contain variable-region domains and retain antigen-binding capability (see Figure 24-8). The Fc portion contains constant-region domains and determines effector functions.
- Immunoglobulins are divided into classes based on the constant regions of the heavy chains they carry (see Figure 24-9). In mammals there are five major classes: IgM, IgD, IgG, IgA, IgE; the corresponding heavy chains are referred to as μ , δ , γ , α , and ϵ . There are two major classes of light chain, κ and λ , again characterized by the attributes of their constant regions.
- Each individual B lymphocyte expresses an immunoglobulin of unique sequence and is therefore uniquely specific for a particular antigen. Upon recognition of antigen, only a B lymphocyte that bears a receptor specific for it will be activated and expand clonally (clonal selection) (see Figure 24-11).
- The antigen specificity of antibodies is conferred by their variable domains, which contain regions of high variability, called hypervariable or complementarity-determining regions (see Figure 24-12a). These hypervariable regions are positioned at the tip of the variable domain, where they can make specific contacts with the antigen for which a particular antibody is specific.
- The repeating domains that make up immunoglobulin molecules have a characteristic three-dimensional structure, the immunoglobulin fold: It consists of two β pleated sheets held together by a disulfide bond (see Figure 24-12b). The immunoglobulin fold is widespread in evolution and is found in many proteins other than antibodies, including an important class of cell-adhesion molecules.
- The constant regions endow antibodies with unique functional properties or effector functions, such as the capacity to bind complement, the ability to be transported across epithelia, or the ability to interact with receptors specific for the Fc portion of immunoglobulins.

24.3 Generation of Antibody Diversity and B-Cell Development

Pathogens have short replication times, are quite diverse in their genetic makeup, and evolve quickly, generating even more antigenic variation. An adequate defense must thus be capable of mounting an equally diverse response. Antibodies fulfill this role. B cells, which are responsible for antibody production, make use of a unique mechanism by which the genetic information required for synthesis of immunoglobulin heavy and light chains is stitched together from separate DNA sequence elements, or Ig gene segments, to create a functional transcriptional unit. The act of recombination that combines Ig gene segments itself dramatically expands the variability in sequence precisely where these genetic elements are joined together. This mechanism of generating a diverse array of antibodies is fundamentally different from meiotic recombination, which occurs only in germ cells, and from alternative splicing of exons (Chapter 8). Because this recombination mechanism occurs in somatic cells but not in germ cells, it is known as *somatic gene rearrangement* or *somatic recombination*.

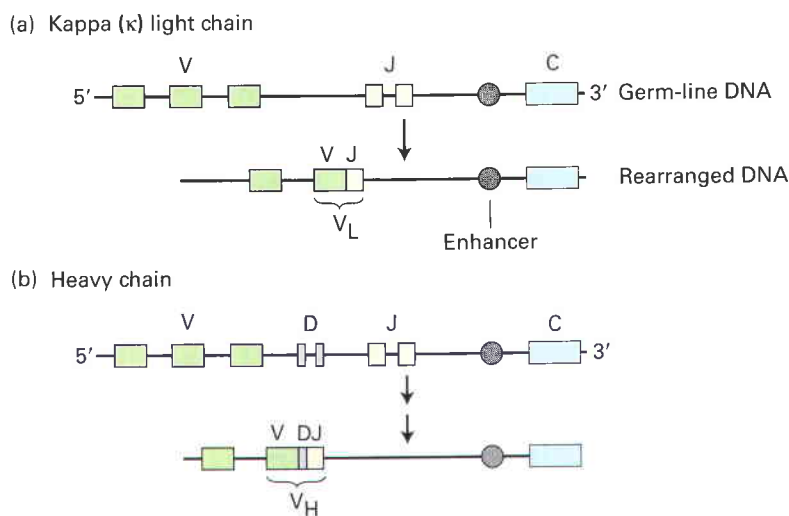

A Functional Light-Chain Gene Requires Assembly of V and J Gene Segments

Immunoglobulin genes encoding intact immunoglobulins do not exist already assembled in the genome, ready for expression. Instead, the required gene segments are brought together and assembled in the course of B-cell development

(Figure 24-14). Although the rearrangement of heavy-chain genes precedes the rearrangement of light-chain genes, we discuss light-chain genes first because of their less complex organization.

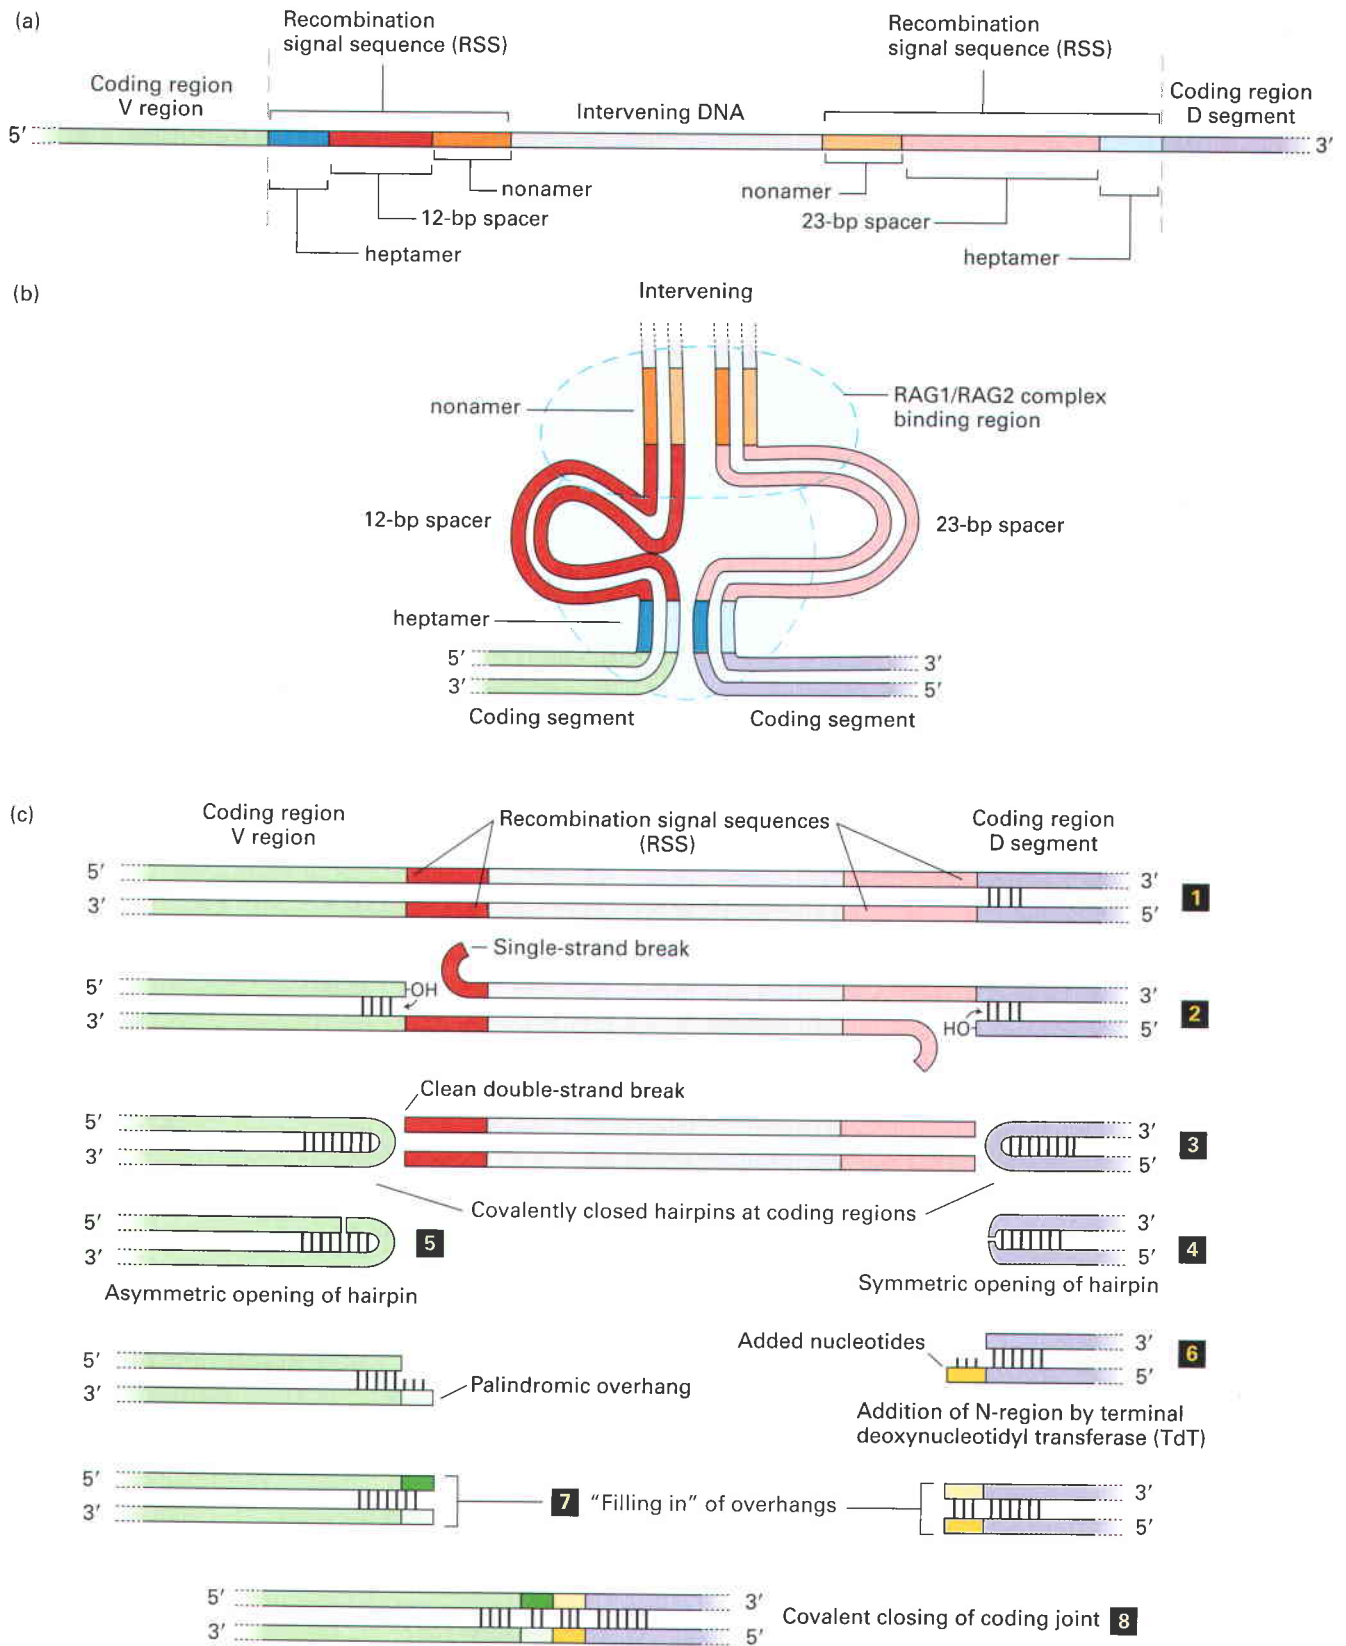

The immunoglobulin light chains are encoded by clusters of V gene segments, followed at some distance downstream by a single C segment. Each V gene segment carries its own promoter sequence and encodes the bulk of the light-chain variable region, although a small piece of the nucleotide sequence encoding the light-chain variable region is missing from the V gene segment. This missing portion is provided by one of the multiple J segments located between the V segments and the single C segment in the unrearranged κ light-chain locus (see Figure 24-14a). In the course of B-cell development, commitment to a particular V gene segment—a random process—results in its juxtaposition with one of the J segments, again a random choice, forming an exon encoding the entire light-chain variable region (V_L). The act of recombination not only generates an intact and functional light-chain gene, but also places the promoter sequence of the rearranged gene within controlling distance of enhancer elements required for its transcription. Only a rearranged light-chain gene is transcribed.

Recombination Signal Sequences Detailed sequence analysis of the light-chain and heavy-chain loci revealed a conserved sequence element at the 3' end of each V gene segment. This conserved element, called a *recombination signal sequence (RSS)*, is composed of heptamer and nonamer sequences separated by a 23-bp spacer. At the 5' end of each

▲ **FIGURE 24-14 Overview of somatic gene rearrangement in immunoglobulin DNA.** The stem cells that give rise to B cells contain multiple gene segments encoding portions of immunoglobulin heavy and light chains. During development of a B cell, somatic recombination of these gene segments yields functional light-chain genes (a) and heavy-chain genes (b). Each V gene segment carries its own promoter. Rearrangement brings an enhancer close enough to the combined VJ sequence to activate transcription. The light-

chain variable region (V_L) is encoded by two joined gene segments, and the heavy-chain variable region (V_H) is encoded by three joined segments. Note that the chromosomal regions encoding immunoglobulins contain many more V, D, and J segments than shown. Also, the κ light-chain locus contains a single constant (C) segment, as shown, but the heavy-chain locus contains several distinct C segments (not shown) corresponding to the immunoglobulin isotypes.

J element, there is a similarly conserved RSS that contains a 12-bp spacer (Figure 24-15a). The 12- and 23-bp spacers separate the conserved heptamer and nonamer sequences by one and two turns of the DNA helix, respectively.

Somatic recombination is catalyzed by the RAG1 and RAG2 recombinases, which are expressed only in lymphocytes. Juxtaposition of the two gene segments to be joined is stabilized by the RAG1/RAG2 complex (Figure 24-15b).

◀ **FIGURE 24-15 Mechanism of rearrangement of immunoglobulin gene segments via deletional joining.** This example depicts joining of a V segment and a D segment. D segments are present in the heavy-chain, but not light-chain, locus (see Figure 24-14b.) (a) Location of the DNA elements involved in somatic recombination of immunoglobulin gene segments. At the 3' end of all V gene segments is a conserved recombination signal sequence (RSS) composed of a heptamer, a 12-bp spacer, and a nonamer. Each of the D segments with which a V can recombine possess at their 5' end a similar RSS with a 23-bp spacer. The nonamer and heptamer sequences at the 5' end of D are complementary and antiparallel to those found at the 3' end of each V when read on the same (top) strand. (b) Hypothetical model of how two coding regions to be joined may be arranged spatially, stabilized by the RAG1 and RAG2 recombinase complex. Both strands of the DNA are shown. (c) Events in deletional joining of V and D coding regions. The germ-line DNA (1) is folded, bringing the segments to be joined close together and the RAG1/RAG2 complex makes single-stranded cuts at the boundaries between the coding sequences and RSSs (2). The free 3' -OH groups attack the complementary strands, creating a covalently closed hairpin at each coding end and a clean double-stranded break at each boundary with a RSS (3). The hairpins are opened, either symmetrically (4), as shown for the J segment, or asymmetrically (5), as shown for the V segment. Terminal deoxynucleotidyl transferase adds nucleotides in a template-independent manner to symmetrically opened hairpins (6, right), generating an overhang (yellow) of unpaired nucleotides of random sequence; asymmetric opening automatically creates a palindromic overhang (6, left). The unpaired overhangs at the ends of both the V and D coding regions are filled in by DNA polymerase (7) or may be excised by an exonuclease. DNA ligase IV joins the two segments generated from the V and D coding regions (8). Rearrangements of light-chain V and J segments occur by the same mechanism except that N-region addition does not take place. See text for additional discussion.

The recombinases then make a single-stranded cut at the exact boundary of each coding sequence and its adjacent RSS. Only gene segments that possess heptamer-nonamer RSSs with spacers of different length can engage in this type of rearrangement (the so-called 12/23 bp spacer rule). Each newly created -OH group then executes a nucleophilic attack on the complementary strand, creating a covalently closed hairpin for each of the two coding ends, and double-strand breaks at the ends of the RSSs. Protein complexes that include the Ku70 and Ku80 proteins hold this complex together, so that the ends about to be joined remain in close proximity. The RSS ends are then covalently joined without loss or addition of nucleotides, creating a circular reaction product containing the intervening DNA, which is lost from the locus altogether. The hairpin ends of the coding segments undergoing recombination then are opened and finally joined as depicted in Figure 24-15c, completing the recombination process.

The recombination mechanism just described, called *deletional joining*, occurs when the V gene segment involved has the same transcriptional orientation as the other gene segments at the light-chain locus. Some V gene segments, however, have the opposite transcriptional orientation. These are joined to J segments by a mechanism, termed *inversional joining*, in which the V segment is inverted and the intervening DNA and RSSs are not lost from the locus.

Defects in the synthesis of RAG proteins obliterates the possibility of somatic gene rearrangements. As described below, the rearrangement process is essential for B-cell development; consequently, RAG deficiency leads to the complete absence of B cells. People with defects in RAG gene function suffer from severe immunodeficiency.

Junctional Imprecision In addition to the sequence variability created by the random selection of V and J gene segments to join, processing of the intermediates created in the course of recombination provide additional means for expanding the variability of immunoglobulin sequences. This additional variability is created at the junction of the segments to be joined. The opening of the hairpins at the coding ends is a key step in this process: this opening may occur symmetrically or asymmetrically (see Figure 24-15, 4 and 5). The protein Artemis, whose function requires the catalytic subunit of DNA-dependent protein kinase, carries out opening of the hairpins.

If opening of a hairpin is asymmetric, a short, single-stranded palindrome sequence is generated. Filling in of this overhang by DNA polymerase results in the addition of several nucleotides, called *P-nucleotides*, that were not part of the original coding region of the gene segment in question. Alternatively, the overhang may be removed by exonucleolytic attack, resulting in the removal of nucleotides from the original coding region. These possibilities apply equally to the V and the J coding regions. Symmetric opening of a hairpin retains all the original coding information. However, even if the hairpin is opened symmetrically, the ends of the DNA molecule tend to breathe, creating short single-stranded sequences, which also may be attacked exonucleolytically, resulting in removal of nucleotides.

Once the hairpins have been opened and the coding ends processed, the ends are ligated together by DNA ligase IV and XRCC4, generating a functional light-chain gene. Inherent in the rearrangement process is *junctional imprecision* resulting in part from the addition and loss of nucleotides at the coding joints. Whenever a V and a J segment recombine, the sequence and reading frame of the VJ product cannot be predicted. Only one in three recombination reactions results in a reading frame that is compatible with light-chain synthesis.

Light-chain diversity therefore arises not only from the combinatorial usage of V and J gene segments, but also from junctional imprecision. Inspection of the three-dimensional structure of the light chain shows that the highly diverse joint, generated as a consequence of junctional imprecision, forms part of a loop—hypervariable region 3 (HV3)—that projects into the antigen-binding site and makes contact with antigen (see Figure 24-12b).

Rearrangement of the Heavy-Chain Locus Involves V, D, and J Gene Segments

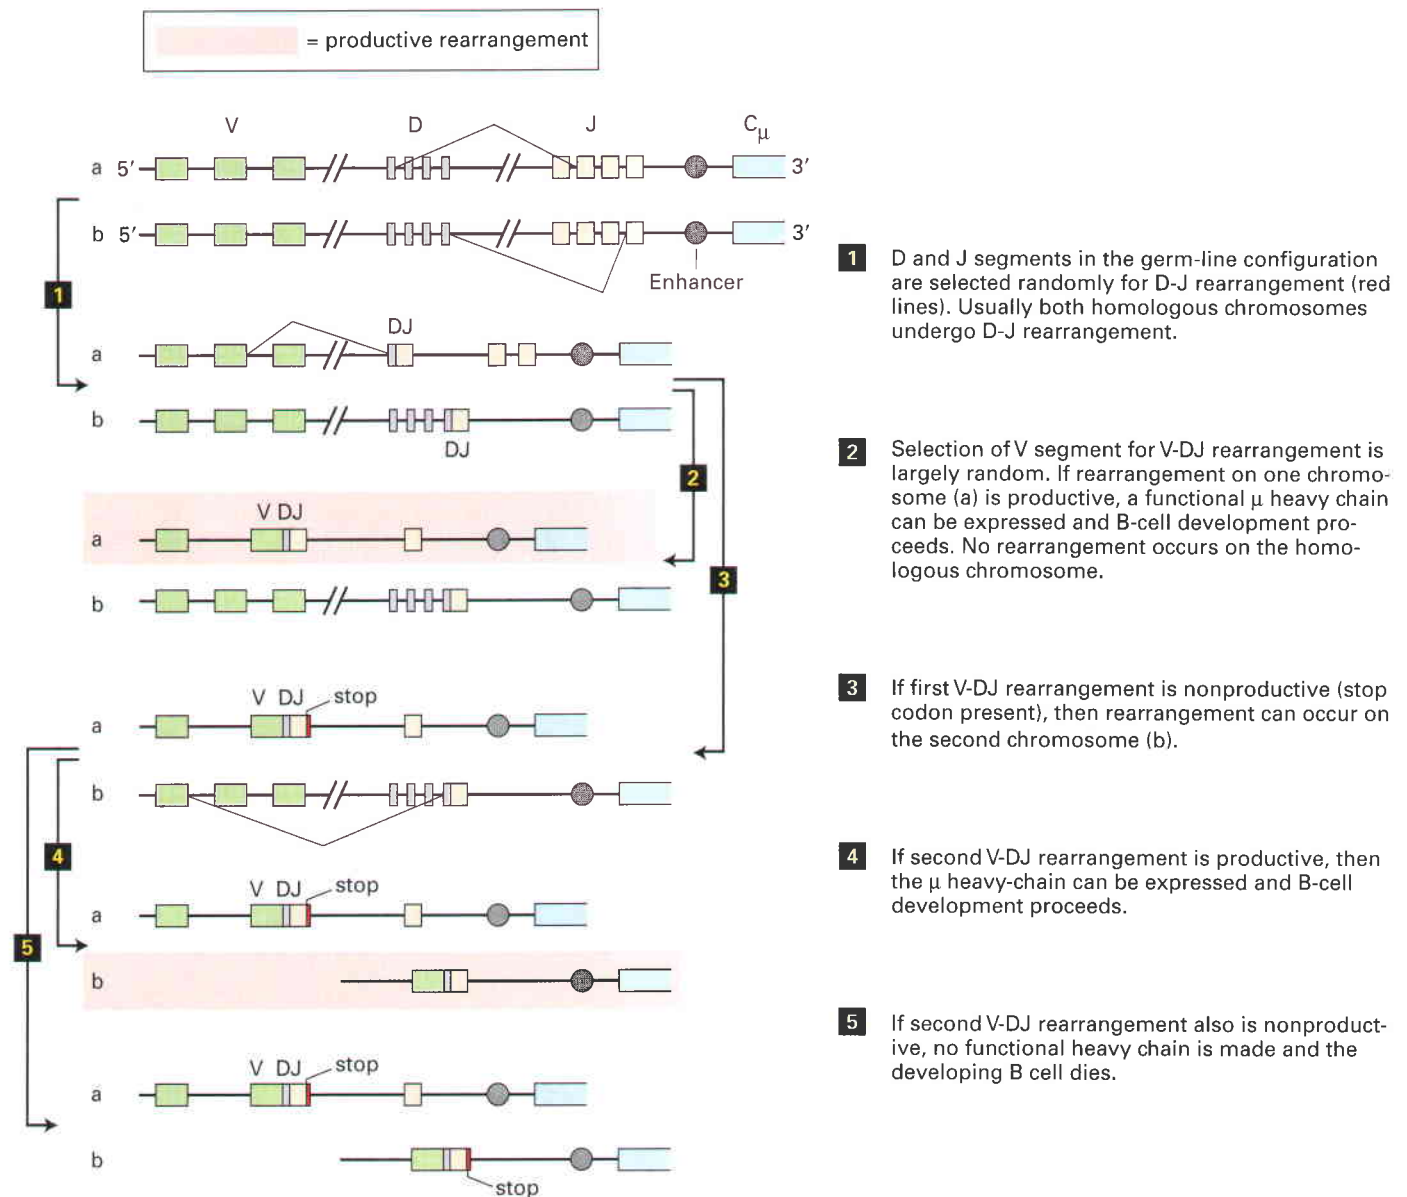

The organization of the heavy-chain locus is more complex than that of the κ light-chain locus. The heavy-chain locus contains not only a large tandem array of V gene segments (each equipped with its own promoter) and multiple J elements, but

also multiple D (diversity) segments (see Figure 24-14b). Somatic recombination of a V, D, and J segment generates a rearranged sequence encoding the heavy-chain variable region (V_H).

At the 3' end of each V gene segment in heavy-chain DNA, there are conserved heptamer and nonamer sequences separated by spacer DNA, similar to the recombination signal sequences (RSSs) in light-chain DNA. These RSSs are also found in complementary and antiparallel configuration at the 5' end and the 3' end of each D segment (see Figure 24-15(a)). The J segments are similarly equipped at their 5'

end with the requisite RSS. The spacer lengths in these RSSs are such that D segments can join to J segments, and V segments to already rearranged DJ segments. However, neither direct V to J nor D to D joining is allowed in view of the 12/23 heptamer-nonamer rule. Heavy-chain rearrangements proceed via the same mechanisms described above for light-chain rearrangements.

In the course of B-cell development, the heavy-chain locus always rearranges first, starting with D-J rearrangements. D-J rearrangement is followed by V-DJ rearrangement (Figure 24-16). In the course of D-J and V-DJ rearrangements, terminal

▲ FIGURE 24-16 Somatic recombination of the heavy-chain locus. The immunoglobulin heavy-chain locus includes multiple V, D, and J gene segments that must be rearranged to form a V-region coding sequence. The two copies of the heavy-chain locus present on homologous chromosomes (a and b) are depicted. D to J rearrangements occur first (**1**), on one or on both chromosomes carrying the heavy-chain locus. A V segment then rearranges with the newly rearranged DJ segment on one chromosome. If this

rearrangement is productive (**2**), further rearrangement ceases, and B-cell development proceeds. If the first V to DJ recombination is nonproductive (i.e., introduces an inappropriate stop codon), the second chromosome may rearrange (**3**). If the second recombination is productive (**4**), then B-cell development proceeds. However, if the second V to DJ recombination also is nonproductive (**5**), the developing B cell dies.

deoxynucleotidyltransferase (TdT) may add nucleotides to free 3' OH ends of DNA in a template-independent fashion. Up to a dozen or so nucleotides, called the *N-region*, may be added, generating additional sequence diversity at the junctions whenever D-J and V-DJ rearrangements occur (see Figure 24-15, step 6). Only one in three rearrangements yields the proper reading frame for the rearranged VDJ sequence. If the rearrangement yields a sequence encoding a functional protein, it is called productive. Although the heavy-chain locus is present on two homologous chromosomes, only one productive rearrangement is permitted, as discussed below.

An enhancer located downstream of the cluster of J segments and upstream of the μ constant-region segment activates transcription from the promoter at the 5' end of the rearranged VDJ sequence (see Figure 24-16). Splicing of the primary transcript produced from the rearranged heavy-chain gene generates a functional mRNA encoding the μ heavy chain. For both immunoglobulin heavy- and light-chain genes, somatic recombination places the promoters upstream of the V segments within functional reach of the enhancers necessary to allow transcription, so that only rearranged VJ and VDJ sequences, and not the V segments that remain in the germ-line configuration, are transcribed.

Somatic Hypermutation Allows the Generation and Selection of Antibodies with Improved Affinities

In addition to the diversity created by somatic recombination and junctional imprecision, antigen-activated B cells can undergo *somatic hypermutation*. Upon receipt of proper additional signals, most of which are provided by T cells, expression of activation-induced deaminase (AID) is turned on. This enzyme deaminates cytosine residues to uracil. When a B cell that carries this lesion replicates, it may place an adenine on the complementary strand, thus generating a G-to-A transition (see Figure 4-35). Alternatively, the uracil may be excised by DNA glycosylase to yield an abasic site. These abasic sites, when copied, give rise to possible transitions as well as a transversion, unless the nucleotide opposite the gap is chosen to be the original G that paired with the cytosine target. Mutations thus accumulate with every successive round of B-cell division, yielding numerous mutations in the rearranged VJ and VDJ segments. Many of these mutations are deleterious, in that they reduce the affinity of the encoded antibody for antigen, but some improve the encoded antibody's affinity for antigen. B cells carrying affinity-increasing mutations have a selective advantage when they compete for the limited amount of antigen that evokes clonal selection (see Figure 24-11). The net result is generation of a B-cell population whose antibodies, as a rule, show a higher affinity for the antigen.

In the course of an immune response or upon repeated immunization, the antibody response exhibits *affinity maturation*, an increase in the average affinity of antibodies for antigen, as the result of somatic hypermutation. Antibodies produced during this phase of the immune response display affinities for antigen in the nanomolar (or better) range. For reasons that are not understood, the activity of activation-

induced deaminase is focused mostly on rearranged VJ and VDJ segments, and this targeting may therefore require active transcription. The entire process of somatic hypermutation is strictly antigen dependent and shows an absolute requirement for interactions between the B cell and certain T cells.

B-Cell Development Requires Input from a Pre-B Cell Receptor

As we have seen, B cells destined to make immunoglobulins must rearrange the necessary gene segments to assemble a functional heavy- and light-chain gene. These rearrangements occur in a carefully ordered sequence during development of a B cell, starting with heavy-chain rearrangements. Moreover, the rearranged heavy-chain is first used to build a membrane-bound receptor that executes a cell fate decision necessary to drive further B-cell development (and antibody synthesis).

Successful rearrangement of V, D, and J segments in the heavy-chain locus allows synthesis of a μ chain. B cells at this stage of development are called *pre-B cells*, as they have not yet completed assembly of a functional light-chain gene and therefore cannot engage in antigen recognition. The newly rearranged heavy-chain gene encodes the μ polypeptide, which becomes part of a signaling receptor whose expression is essential for B-cell development to proceed in orderly fashion. The μ chain made at this stage of B cell development is a membrane-bound version. Following engagement with antigen, the B cell switches to producing soluble, secreted immunoglobulins from the same transcription unit, as we describe below.

In pre-B cells, newly made μ chains form a complex with so-called surrogate light chains, composed of two subunits, $\lambda 5$ and VpreB (Figure 24-17). The μ chain itself possesses no cytoplasmic tail and is therefore incapable of recruiting cytoplasmic components for the purpose of signal transduction. Instead, early B cells express two auxiliary transmembrane proteins, called $Ig\alpha$ and $Ig\beta$, each of which carries in its cytoplasmic tail an immunoreceptor tyrosine-based activation motif, or ITAM. The entire complex including $Ig\alpha$ and $Ig\beta$ constitutes the *pre-B cell receptor (pre-BCR)*. Engagement of this receptor by suitable signals results in recruitment and activation of a Src family tyrosine kinase, which phosphorylates tyrosine residues in the ITAMs. In their phosphorylated form, ITAMs recruit other molecules essential for signal transduction (see below). Because no functional light chains are yet part of this receptor, it is incapable of antigen recognition.

The pre-B cell receptor has several important functions. First, it shuts off expression of the RAG recombinases, so rearrangement of the other (allelic) heavy-chain locus cannot occur. This phenomenon, called *allelic exclusion*, ensures that only one of the two available copies of the heavy-chain locus will be rearranged and thus expressed. Second, because of the association of the pre-B cell receptor with $Ig\alpha$ and $Ig\beta$, the receptor becomes a functional signal-transduction unit. The pre-BCR also initiates cell proliferation and so expands the numbers of those B cells that have undergone productive D-J and V-DJ recombination.

▲ FIGURE 24-17 Structure of the pre-B cell receptor and its role in B-cell development. Successful rearrangement of V, D, and J heavy-chain gene segments allows synthesis of membrane-bound μ heavy chains in the endoplasmic reticulum (ER) of a pre-B cell. At this stage, no light-chain gene rearrangement has occurred. Newly made μ chains assemble with surrogate light chains, composed of $\lambda 5$ and VpreB, to yield the pre-B cell receptor, pre-BCR (1). This receptor drives proliferation of those B cells that carry it. It also suppresses rearrangement of the heavy-chain locus on the other chromosome

and so mediates allelic exclusion. In the course of proliferation, the synthesis of $\lambda 5$ and VpreB is shut off (2), resulting in “dilution” of the available surrogate light chains and reduced expression of the pre-BCR. As a result, rearrangement of the light-chain loci can proceed (3). If this rearrangement is productive, the B cell can synthesize light chains and complete assembly of the B-cell receptor (BCR), comprising a membrane-bound IgM and associated Ig α and Ig β . The B cell is now responsive to antigen-specific stimulation.

In the course of this expansion, expression of the surrogate light-chain subunits, VpreB and $\lambda 5$, is turned off. The progressive dilution of VpreB and $\lambda 5$ with every successive cell division allows reinitiation of expression of the RAG enzymes, which now target the κ or λ light-chain locus for recombination. A productive V-J rearrangement also shuts off rearrangement of the allelic locus (allelic exclusion). Upon completion of a successful V-J light-chain rearrangement, the B cell can make both μ heavy chains and κ or λ light chains, and assemble them into a functional B-cell receptor (BCR), which can recognize antigen (see Figure 24-17).

Once a B cell expresses a complete BCR on its cell surface, all subsequent steps in B-cell activation and differentiation involve recognition of the antigen for which that BCR is specific. The BCR not only plays a role in driving B-cell proliferation upon successful encounter with antigen, but also functions as a device for ingesting antigen, an essential step that allows the B cell to process the acquired antigen and convert it into a signal that sends out a call for assistance by T lymphocytes. This antigen-presentation function of B cells is described in later sections.

During an Adaptive Response, B Cells Switch from Making Membrane-Bound Ig to Making Secreted Ig

As just described, the B-cell receptor (BCR), a membrane-bound IgM, provides a B cell with the ability to recognize a particular antigen, an event that triggers clonal selection and proliferation of that B cell, thus increasing the number of B cells specific for the antigen (see Figure 24-11). However, key functions of immunoglobulins, such as neutralization of antigen or killing of bacteria, require that these products be released by the B cell, so that they may accumulate in the extracellular environment and act at a distance from the site where they were produced.

The choice between the synthesis of membrane-bound versus secreted immunoglobulin is made during processing of the heavy-chain primary transcript. As shown in Figure 24-18, the μ locus contains two exons (TM1 and TM2) that together encode a C-terminal domain that anchors IgM in the plasma membrane. One polyadenylation site is found upstream of these exons; a second polyadenylation site is present downstream. If the downstream poly(A) site is chosen,

▲ **FIGURE 24-18 Synthesis of secreted and membrane IgM.** The organization of the μ heavy-chain primary transcript is shown at the top: $C_{\mu 4}$ is the exon encoding the fourth μ constant-region domain; μ_s is a coding sequence unique for secreted IgM; TM1 and TM2 are exons that specify the transmembrane domain of the μ chain. Whether secreted or membrane-bound IgM is made depends on which poly(A) site is selected during processing of the primary

transcript. (a) If the upstream poly(A) site is used, the resulting mRNA includes the entire $C_{\mu 4}$ exon and specifies the secreted form of the μ chain. (b) If the downstream poly(A) site is used, a splice donor site in the $C_{\mu 4}$ exon allows splicing to the transmembrane exons, yielding a mRNA that encodes the membrane-bound form of the μ chain. Similar mechanisms generate secreted and membrane-bound forms of other Ig isotypes. SS = signal sequence.

then further processing yields a mRNA encoding the membrane-bound form of μ . (As described above, this choice is necessary for formation of the B-cell receptor, which includes membrane-bound IgM.) If the upstream poly(A) site is chosen, processing yields the secreted version of the μ chain. Similar arrangements are found for the other Ig constant-region gene segments, each of which can specify either a membrane-bound or a secreted heavy chain.

In the course of B-cell differentiation, the B cell acquires the capacity to switch from the synthesis of exclusively membrane immunoglobulin to the synthesis of secreted immunoglobulin. Terminally differentiated B cells, called *plasma cells*, are devoted almost exclusively to the synthesis of secreted antibodies (see Figure 24-6). Plasma cells synthesize and secrete several thousand antibody molecules per second. It is this ramped up production of secreted antibodies that underlies the effective-

ness of the adaptive immune response in eliminating pathogens. The protective value of antibodies is proportional to the concentration at which they are present in the circulation. Indeed, circulating antibody levels are often used as the key parameter to determine whether vaccination against a particular pathogen has been successful. The ability of plasma cells to establish adequate antibody levels is a function of their ability to secrete large amounts of immunoglobulins and so requires a massive expansion of the endoplasmic reticulum, a hallmark of plasma cells.

B Cells Can Switch the Isotype of Immunoglobulin They Make

In the immunoglobulin heavy-chain locus, the exons that encode the μ chain lie immediately downstream of the rearranged VDJ exon (Figure 24-19, *top*). This is followed by

▲ **FIGURE 24-19 Class switch recombination in the immunoglobulin heavy-chain locus.** Class switch recombination involves switch sites, which are repetitive sequences (colored circles) upstream of the heavy-chain constant-region genes. Recombination requires activation-induced deaminase (AID), assistance by T cells, and cytokines (e.g., IL-4) produced by certain T cells. Recombination

eliminates the segment of DNA between the switch site upstream of μ exons and the constant region to which switching occurs. Class switching generates antibody molecules with the same specificity for antigen as that of the IgM-bearing B cell that mounted the original response, but with different heavy-chain constant-regions and therefore different effector functions.

exons that specify the δ chain. Transcription of a newly rearranged immunoglobulin heavy-chain locus yields a single primary transcript that includes the μ and δ constant regions. Splicing of this large transcript determines whether a μ chain or a δ chain will be produced. Downstream of the μ/δ combination are the exons that together encode all of the other heavy-chain isotypes. Upstream of each cluster of exons (with the exception of the δ locus) encoding the different isotypes are repetitive sequences (switch sites) that are recombination prone, presumably because of their repetitive nature. Because each B cell necessarily starts out with surface IgM, recombination involving these sites, if it occurs, results in a *class switch* from IgM to one of the other isotypes located downstream in the array of constant-region genes (see Figure 24-19). The intervening DNA is deleted.

In the course of its differentiation, a B cell can switch sequentially. Importantly, the light chain is not affected by this process, nor is the rearranged VDJ segment with which the B cell started out on this pathway. Class switch recombination thus generates antibodies with different constant regions, but of identical antigenic specificity. Each immunoglobulin isotype is characterized by its own unique constant region. As discussed previously, these constant regions determine the functional properties of the various isotypes. Class switch recombination is absolutely dependent on the activity of activation-induced deaminase (AID) and the presence of antigen and T cells. Somatic hypermutation and class switch recombination occur concurrently, and their combined effect allows fine tuning of the adaptive immune response with respect to the affinity of the antibodies produced and the effector functions called for.

KEY CONCEPTS OF SECTION 24.3

Generation of Antibody Diversity and B-Cell Development

- Functional antibody-encoding genes are generated by somatic rearrangement of multiple DNA segments at the heavy-chain and light-chain loci. These rearrangements involve V and J segments for immunoglobulin light chains, and V, D, and J segments for immunoglobulin heavy chains (see Figure 24-14).
- Rearrangement of the V and J, as well as of the V, D, and J gene segments is controlled by conserved recombination signal sequences (RSSs), composed of heptamers and nonamers separated by 12- or 23-bp spacers (see Figure 24-15). Only those segments that have spacers of different length can rearrange successfully.
- The molecular machinery that carries out the rearrangement process includes recombinases (RAG1 and RAG2) made only by lymphocytes and numerous other proteins that participate in nonhomologous end joining of DNA molecules in other cell types as well.
- Antibody diversity is created by the random selection of Ig gene segments to be recombined (combinatorial joining) and by the ability of the heavy and light chains produced from rearranged Ig genes to associate with many different

light chains and heavy chains, respectively (combinatorial association).

- Junctional imprecision generates additional antibody diversity at the joints of the gene segments joined during somatic recombination.
- Further antibody diversity arises after B cells encounter antigen as a consequence of somatic hypermutation, which can lead to the selection and proliferation of B cells producing high-affinity antibodies, a process termed affinity maturation.
- During B-cell development, heavy-chain genes are rearranged first, leading to expression of the pre-B cell receptor. Subsequent rearrangement of light-chain genes results in assembly of an IgM membrane-bound B-cell receptor (see Figure 24-17).
- Only one of the allelic copies of the heavy-chain locus and of the light-chain locus is rearranged (allelic exclusion), ensuring that a B cell expresses Ig with a single antigenic specificity.
- Polyadenylation of different poly(A) sites in an Ig primary transcript determines whether the membrane-bound or secreted form of an antibody is produced (see Figure 24-18).
- During an immune response, class switching allows B cells to adjust the effector functions of the immunoglobulins produced but retain their specificity for antigen (Figure 24-19).

24.4 The MHC and Antigen Presentation

Antibodies can recognize antigen without the involvement of any third-party molecules; the presence of antigen and antibody is sufficient for their interaction. Although antibodies contribute to the elimination of bacterial and viral pathogens, it is often necessary to destroy also the infected cells that serve as a source of new virus particles. This task is carried out by T cells with cytotoxic activity. These *cytotoxic T cells* make use of antigen-specific receptors whose genes are generated by mechanisms analogous to those used by B cells to generate immunoglobulin genes. However, antigen recognition is accomplished very differently by T cells than by B cells. The antigen-specific receptors on T cells recognize short snippets of protein antigens, presented to these receptors by membrane glycoproteins encoded by the **major histocompatibility complex (MHC)**. Various antigen-presenting cells, in the course of their normal activity, digest pathogen-derived (and self) proteins and then “post” these protein snippets (peptides) to their cell surface in a physical complex with an MHC protein. T cells can inspect these complexes, and if they detect a pathogen-derived peptide, the T cells take appropriate action, which may include killing the cell that carries the MHC–peptide complex.

MHC proteins, which commonly are called **MHC molecules**, also facilitate communication between T cells and B cells. B cells do not usually engage in production of secreted antibodies unless they receive assistance from another subset of T cells, called helper T cells. These T cells also use

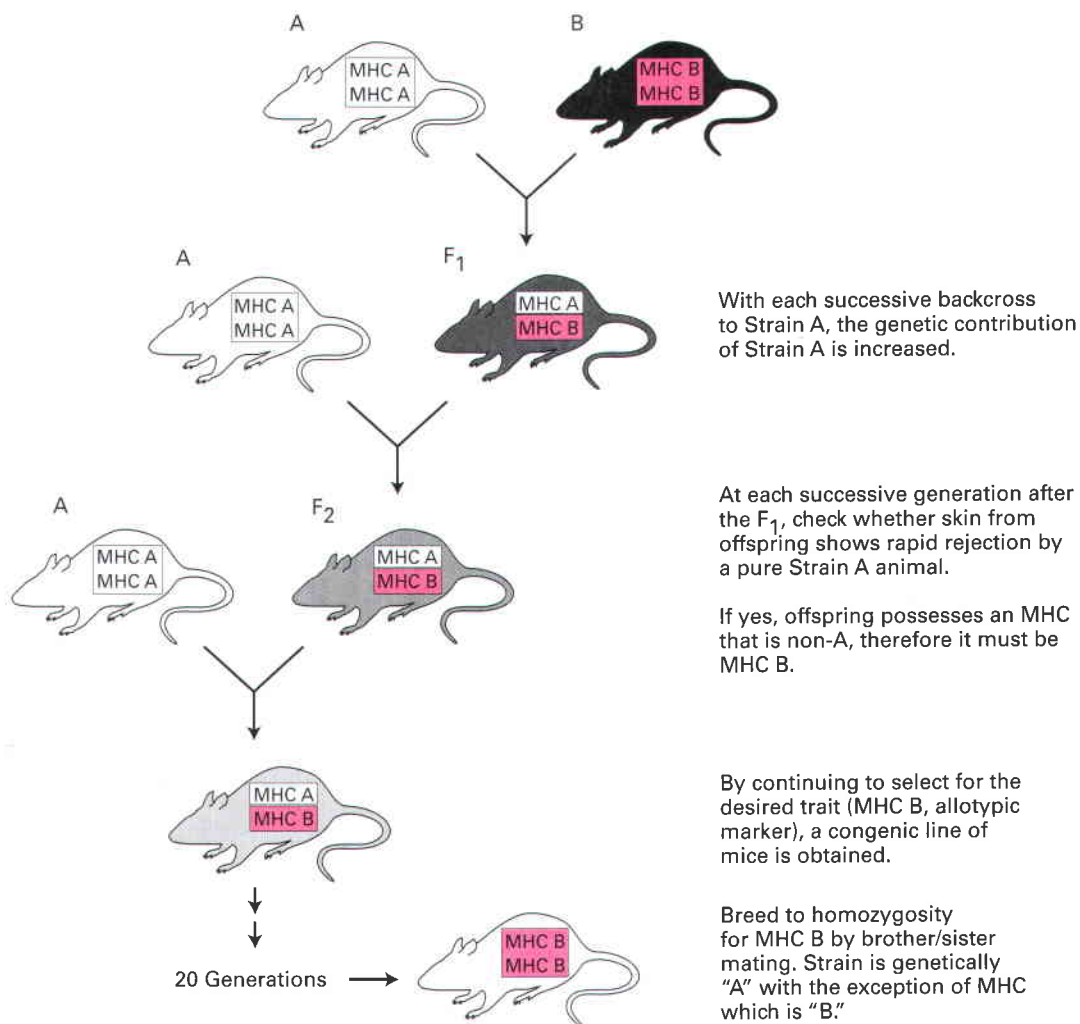

antigen-specific receptors to recognize MHC-peptide complexes. In this section, we describe the MHC and the proteins it encodes, and then examine how these MHC molecules are involved in antigen recognition.

The MHC Determines the Ability of Two Unrelated Individuals of the Same Species to Accept or Reject Grafts

The major histocompatibility complex was discovered, as its name implies, as the genetic locus that controls acceptance or rejection of grafts. At a time when tissue culture had not yet been developed to the stage where tumor-derived cell lines could be propagated in the laboratory, investigators relied on serial passage *in vivo* of tumor tissue. It was quickly observed that a tumor that arose spontaneously in one

inbred strain of mice could be propagated successfully in the strain in which it arose, but not in a genetically distinct line of mice. Genetic analysis soon showed that a single major locus was responsible for this behavior. Similarly, transplantation of healthy skin was feasible within the same strain of mice, but not when the recipient was of a genetically distinct background. Genetic analysis of transplant rejection likewise identified a single major locus that controlled acceptance or rejection, which is an immune reaction. As we now know, all vertebrates that possess an adaptive immune system have a genetic region that corresponds to the major histocompatibility complex as originally defined in the mouse.

An important step in discovering the functions of the MHC was development of mice strains *congenic* for the MHC. Congenic strains are genetically identical except for the locus or genetic region of interest. Figure 24-20 outlines

▲ **EXPERIMENTAL FIGURE 24-20** Mice congenic for the major histocompatibility (MHC) are generated by crossing two histo-incompatible strains. Strain A and strain B, which reject each other's grafts, are said to be histo-incompatible and differ at their MHC. The (A × B) F₁ progeny accept grafts from either parental strain. By backcrossing F₁ mice to one of the parental strains (e.g., strain A) for many generations, the contribution of strain A to the genetic material of the resulting offspring will increase. Breeding is

performed such that only those animals that have retained the MHC of strain B are used for breeding. The presence of the strain B MHC is assessed by performing a skin graft onto a strain A recipient. Only if the B-type MHC is present will inbred mice of strain A reject the graft. By performing such backcrosses and assays for the B-type MHC for 20 or more generations, a strain of mice is obtained that is essentially A in its genetic make up, yet retains the MHC of strain B. These mice are said to be congenic for the MHC.

▲ **FIGURE 24-21 Organization of the major histocompatibility complex in mice and humans.** The major loci are depicted with schematic diagrams of their encoded proteins below. Class I MHC proteins are composed of a MHC-encoded single-pass transmembrane glycoprotein in noncovalent association with a small subunit, called β 2-microglobulin, which is not encoded in the MHC and is not membrane bound. Class II MHC proteins consist of two nonidentical single-pass transmembrane glycoproteins, both of which are encoded by the MHC.

how mice strains congenic for the MHC can be generated. Congenic strains are essential tools for assigning complex immunological functions to a particular locus, such as the MHC. As long as it is possible to select for a particular phenotypic trait in the form of an allelic marker (e.g., graft rejection in the case of the MHC), congenic strains may be produced for other loci.

In the mouse, the genetic region that encodes the antigens responsible for a strong graft rejection is called the *H-2 complex* (Figure 24-21a). The initial characterization of the MHC was followed by an appreciation of the genetic complexity of this region. After coarse mapping by standard genetic means (recombination within the MHC), the complete nucleotide sequence of the entire MHC was determined. The typical mammalian MHC contains dozens of genes, many encoding proteins of immunological relevance.

In humans, the discovery of the MHC relied on the characterization of antisera produced in patients who underwent multiple blood transfusions: Antigens expressed on the surface of the genetically nonidentical donor cells provoked an immune response in the recipient. The predominant target antigens recognized by these antisera are encoded by the human MHC, a genetic region also referred to as the *HLA complex* (Figure 24-21b). All vertebrate MHCs encode a highly homologous set of proteins, although the details of

organization and gene content show considerable variation between species.

The human fetus may also be considered a graft: The fetus shares only half of its genetic material with the mother, the other half being contributed by the father. Antigens encoded by this paternal contribution may differ sufficiently from their maternal counterparts to elicit an immune response in the mother. In the course of pregnancy, fetal cells that slough off into the maternal circulation stimulate the maternal immune system to mount an antibody response against these paternal antigens. The antibodies recognize structures encoded by the human MHC. The fetus itself is spared rejection because of the specialized organization of the placenta, which prevents initiation of an immune response by the mother against fetal tissue.

The Killing Activity of Cytotoxic T Cells Is Antigen Specific and MHC Restricted

Clearly the function of MHC molecules is not to prevent the exchange of surgical grafts. MHC molecules play an essential role in the recognition of virus-infected cells by cytotoxic T cells; these cells also are called cytotoxic T lymphocytes (CTLs). In virus-infected cells, MHC molecules interact with protein fragments derived from viral pathogens and display these on the cell surface where cytotoxic T cells, charged with eliminating the infection, can recognize them.

Mice that have recovered from a particular virus infection are a ready source of cytotoxic T cells that can recognize and kill target cells infected with the same virus. The radioactive chromium (^{51}Cr) release assay can be used to detect the presence of cytotoxic T cells in single-cell suspensions prepared from the spleen of an animal that has cleared an infection (Figure 24-22a). If T cells are obtained from a mouse that successfully cleared an infection with influenza virus, cytotoxic activity is observed against influenza-infected target cells, but not against uninfected controls (Figure 24-22b). Moreover, the influenza-specific cytotoxic T cells will not kill target cells infected with a different virus, such as vesicular stomatitis virus. Cytotoxic T cells can even discriminate between closely related strains of influenza virus, and can do so with pinpoint precision: Differences of a single amino acid in the viral antigen may suffice to avoid recognition and killing by cytotoxic T cells. These experiments show that cytotoxic T cells are truly antigen-specific and do not simply recognize some attribute that is shared by all virus-infected cells, regardless of the identity of the virus.

In this example, it is assumed that the T cells harvested from an influenza-immune mouse are assayed on influenza-infected target cells derived from the identical strain of mouse (strain a). However, if target cells from a completely unrelated strain of mouse (strain b) are infected with the same strain of influenza and used as targets, the cytotoxic T cells from the strain a mouse are unable to kill the infected strain b target cells (see Figure 24-22b, **3** vs. **4**). It is therefore not sufficient that the antigen (an influenza-derived protein) is present; recognition by cytotoxic T cells is restricted by strain-specific elements. By making use of MHC congenic

▲ EXPERIMENTAL FIGURE 24-22 Chromium (^{51}Cr) release assay allows the direct demonstration of the cytotoxicity and specificity of cytotoxic T cells in a heterogeneous population of cells. (a) A suspension of spleen cells, containing cytotoxic (killer) T cells is prepared from mice that have been exposed to a particular virus (e.g., influenza virus) and have cleared the infection. Target cells obtained from the same strain are infected with the identical virus or left uninfected. After infection, cellular proteins are labeled nonspecifically by incubation of the target-cell suspension with ^{51}Cr . Upon incubation of radiolabeled target cells with the suspension of T cells, killing of target cells results in release of the ^{51}Cr -labeled proteins. Uninfected target cells are not killed and retain their

radioactive contents. Lysis of cells by cytotoxic T cells can therefore be readily detected and quantitated by measuring the radioactivity released into the supernatant. (b) Cytotoxic T lymphocytes (CTLs) harvested from mice that have been infected with virus X can be tested against various target cells to determine the specificity of CTL-mediated killing. CTLs capable of lysing virus X-infected target cells (2) cannot kill uninfected cells (1) or cells infected with a different virus, Y (3). When these CTLs are tested on virus X-infected targets from a strain that carries an altogether different MHC type (b), again no killing is observed (4). Cytotoxic T-cell activity is thus virus specific and restricted by the MHC.

strains, the genes that encode these restricting elements were mapped to the MHC. Thus cytotoxic T cells from one mouse strain immune to influenza will kill influenza-infected target cells from another strain only if the two strains match at the MHC for the relevant MHC molecules. This phenomenon is therefore known as *MHC restriction*.

T Cells with Different Functional Properties Are Guided by Two Distinct Classes of MHC Molecules

The MHC encodes two types of glycoproteins essential for immune recognition, commonly called *class I* and *class II*

MHC molecules. A comparison of the genetic maps of the mouse and human MHCs shows the presence of several class I MHC genes and several class II MHC genes, even though their arrangement shows variation between the different species (see Figure 24-21). In addition to the class I and class II MHC molecules, the MHC encodes key components of the antigen-processing and presentation machinery. Finally, the typical vertebrate MHC also encodes key components of

◀ **FIGURE 24-23 Three-dimensional structure of class I and class II MHC molecules.** (a) Shown here is the structure of a class I MHC molecule with bound peptide as determined by x-ray crystallography. The portion of a class I MHC molecule that binds peptide consists of a β sheet composed of eight β strands and flanked by two α helices. The peptide-binding cleft is formed entirely from the MHC-encoded large subunit, which associates noncovalently with the small subunit (β 2-microglobulin) encoded elsewhere. (b) Class II MHC molecules are structurally similar to class I molecules, but with several important distinctions. Both the α and β subunits of class II MHC molecules are MHC encoded and contribute to formation of the peptide-binding cleft. The peptide-binding cleft of class II MHC molecules accommodates a wider range of peptide sizes than that of class I molecules. [Part (a) based on D. N. Garboczi, 1996 *Nature* **384**:134, Part (b) based on J. Hennecke et al., 2000, *EMBO* **19**: 5611.]

the complement cascade. Class I and Class II MHC molecules are recognized by different populations of immune system cells and therefore serve different functions.

As should be clear from the experiments outlined in Figure 24-22, cytotoxic T cells are guided in the recognition of their targets by MHC molecules. These T cells mostly use class I MHC molecules as their restriction elements, and also are characterized by the presence of the CD8 glycoprotein marker on their surface. Most, if not all, nucleated cells constitutively express class I MHC molecules and can support replication of viruses. Cytotoxic T cells recognize and kill the infected targets via the expressed class I MHC molecules that display virus-derived antigen.

As mentioned previously, B cells do not undergo final differentiation into antibody-secreting plasma cells without assistance from another subset of T cells, the *helper T cells* (or T helper cells). Helper T cells express on their surface the CD4 glycoprotein marker and use class II MHC molecules as restriction elements. The constitutive expression of class II MHC molecules is confined to so-called *professional* antigen-presenting cells, including B cells, dendritic cells, and macrophages. (Several other cell types, some in epithelia, can be induced to express class II MHC molecules, but we will not discuss these.)

The two major groups of functionally distinct T lymphocytes—cytotoxic T cells and helper T cells—can thus be distinguished based on the unique profile of membrane proteins displayed at the cell surface and by the MHC molecules used as restriction elements:

- Cytotoxic T cells: CD8 marker; class I MHC restricted
- Helper T cells: CD4 marker; class II MHC restricted

Both CD4 and CD8 belong to the immunoglobulin (Ig) superfamily of proteins, which all include one or more Ig domains. The B-cell and T-cell receptors, polymeric IgA receptor, and many cell-adhesion molecules (Chapter 19) also belong to the Ig superfamily. The molecular basis for the strict correlation between expression of CD8 and utilization of class I MHC molecules or between expression of CD4 and utilization of class II MHC molecules as the restriction element will become evident once the structure and mode of action of MHC molecules has been described.

MHC Molecules Bind Peptide Antigens and Interact with the T-Cell Receptor

Both class I and class II MHC molecules are highly *polymorphic*; that is, many allelic variants exist among individuals of the same species. Both classes of MHC molecules also are structurally similar in many respects as are their interactions with peptides and the T-cell receptor (Figure 24-23).

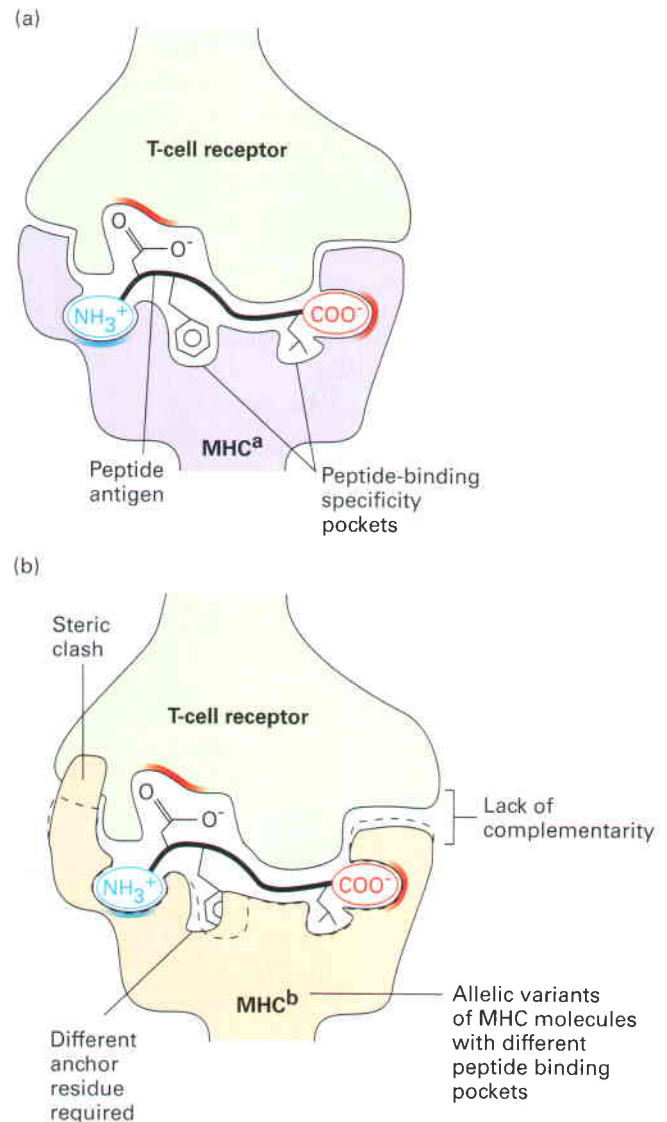

Class I MHC Molecules Class I MHC molecules belong to the Ig superfamily and consist of two polypeptides. The larger subunit is a type I membrane glycoprotein (see Figure 13-10) encoded by the MHC. The smaller β 2-microglobulin subunit is not encoded by the MHC and corresponds in structure to a free Ig domain. Originally purified from human leukocytes by digestion with papain, which releases the extracellular portion of the class I MHC molecules in intact form, these proteins are now produced by recombinant DNA technology procedures and have become important tools for the detection of antigen-specific T cells.

Implicit in the notion that MHC molecules are the targets of graft rejection is their structural variation, attributable to inherited variation (genetic polymorphism): If a recipient rejects a graft, the recipient's immune system must be capable of distinguishing unique features of the donor MHC molecules present on the graft. In fact, the genes encoded by the MHC are among the most polymorphic currently known, with over 2000 distinct allelic products identified in humans. The class I MHC molecules in humans are encoded by the HLA-A, HLA-B and HLA-C loci (see Figure 24-21). Each unique allele is designated by a numerical suffix for that particular locus (e.g., HLA-A2 and HLA-A28 represent two distinct HLA-A allelic products). In the mouse, the class I MHC molecules are encoded by the H-2K and H-2D loci. A superscript is used to denote the identity of the allelic products (e.g., H-2K^b and H-2K^k represent two allelic variants of the H-2K locus product).

The three-dimensional structure of class I MHC molecules reveals two membrane-proximal Ig-like domains. These domains support an eight-stranded β -pleated sheet topped by two α helices. Jointly the β sheet and the helices create a cleft, closed at both ends, in which a peptide binds (see Figure 24-23a). The mode of peptide-binding by a class I MHC molecule requires a peptide of rather fixed length, usually 8 to 10 amino acids, so that the ends of the peptide can be tucked into pockets that accommodate the charged amino and carboxyl groups at the termini. Further, the peptide is anchored into the peptide-binding cleft by means of a small number of amino acid side chains, each of which is accommodated by a pocket in the MHC molecule that neatly fits that particular amino acid residue (Figure 24-24a). On average, two such “specificity pockets” must be filled correctly to allow stable peptide binding. One of these pockets often involves the very C-terminal residue; a second specificity pocket accommodates a residue more central to the peptide. In this manner, a given MHC molecule can accommodate a large number of peptides of diverse sequence, as long as the “anchor” requirements are fulfilled.

The polymorphic residues that distinguish one allelic MHC molecule from another are mostly located in and

around the peptide-binding cleft. These residues therefore determine the architecture of the peptide-binding pocket and hence the specificity of peptide binding. Further, these polymorphic residues affect the surface of the MHC molecule and hence the points of contact with the T-cell receptor. A T-cell receptor designed to interact with one particular class I MHC allele will therefore, as a rule, not interact with unrelated MHC molecules because of their different surface architecture (Figure 24-24b). The CD8 marker functions as

▲ FIGURE 24-24 Peptide binding and MHC restriction.

(a) Peptides that bind to class I molecules are on average 8–10 residues in length, require proper accommodation of the termini, and include two or three residues that are conserved (anchor residues). Positions in class I molecules that distinguish one allele from another (polymorphic residues) occur in and around the peptide-binding cleft. The polymorphic residues in the MHC affect both the specificity of peptide binding and the interactions with T-cell receptors. Successful “recognition” of a peptide antigen–MHC complex by a T-cell receptor requires a good fit among the receptor, peptide, and MHC molecule. (b) Steric clash and a lack of complementarity between anchor residues and the MHC molecule prevent proper binding. T-cell receptors are thus restricted to specific peptide–MHC products.

a co-receptor, binding to conserved portions of the class I MHC molecules. The presence of CD8 thus “sets” the restriction specificity of any mature T cell that bears it.

Class II MHC Molecules The two subunits (α and β) of class II MHC molecules are both type I membrane glycoproteins and belong to the Ig superfamily. The typical mammalian MHC contains several loci that encode class II MHC molecules (see Figure 24-21). Like the large subunit of class I molecules, both the α and β subunits of class II molecules show genetic polymorphism.

The basic three-dimensional design of class II MHC molecules resembles that of class I MHC molecules: Two membrane-proximal Ig-like domains support a peptide-binding portion composed of an eight-stranded β sheet and two α helices (see Figure 24-23b). For class II MHC molecules, the α and β subunits contribute equally to the construction of the peptide-binding cleft. This cleft is open at both ends and thus supports the binding of longer peptides that protrude from it. The mode of peptide binding involves pockets that accommodate specific peptide side chains, as well as contacts between side chains of the MHC molecule with main-chain atoms of the bound peptide. Class II MHC polymorphisms mainly affect residues in and around the peptide-binding cleft, so that the peptide-binding specificity will usually differ among different allelic products.

A T-cell receptor designed to interact with a particular class II MHC molecule will not, as a rule, interact with a different allelic molecule, not only because of the difference in the peptide-binding specificity of the allelic molecules, but also because of the polymorphisms that affect the contact residues with the T-cell receptor. As discussed below, class II MHC molecules evolved to present peptides generated predominantly in endosomes and lysosomes. The interactions between a peptide and class II MHC molecule take place in these organelles, and class II MHC molecules are targeted specifically to those locations after their synthesis in the endoplasmic reticulum.

This targeting is accomplished by means of a chaperone called the invariant chain, a type II membrane glycoprotein (see Figure 13-10). The invariant chain (Ii) plays a key role in the early stages of class II MHC biosynthesis by forming a trimeric structure onto which the class II MHC $\alpha\beta$ heterodimers assemble. The final assembly product thus consists of nine polypeptides: $(\alpha\beta Ii)_3$. The interaction between Ii and the $\alpha\beta$ heterodimer involves a stretch of Ii called the CLIP segment, which occupies the class II MHC peptide-binding cleft. Once the $(\alpha\beta Ii)_3$ complex is assembled, the complex enters the secretory pathway and is diverted to endosomes and lysosomes at the *trans*-Golgi network (see Figure 14-1). The signals responsible for this diversion are carried by the Ii cytoplasmic tail and do not obviously conform to the endosomal targeting or retrieval signals commonly found on lysosomal membrane proteins. Some of the $(\alpha\beta Ii)_3$ complexes are directed straight to the cell surface from which they may be internalized, but the vast majority end up in late endosomes.

As we saw for class I MHC molecules and their CD8 co-receptor, the CD4 co-receptor recognizes conserved features

on class II MHC molecules. Any mature T cell that bears the CD4 co-receptor uses class II MHC molecules for antigen recognition.

Antigen Presentation Is the Process by Which Protein Fragments Are Complexed with MHC Products and Posted to the Cell Surface

The process by which foreign materials enter the immune system is the key step that determines the eventual outcome of a response. A successful adaptive immune response, which includes the production of antibodies and the generation of helper and cytotoxic T cells, cannot unfold without the involvement of professional antigen-presenting cells. Professional antigen-presenting cells include dendritic cells and macrophages, both bone marrow-derived, and B cells. It is these cells that acquire antigen, process it, and then display it in a form that can be recognized by T cells. The pathway by which antigen is converted into a form suitable for T-cell recognition is referred to as *antigen processing and presentation*.

The class I MHC pathway focuses predominantly on presentation of proteins synthesized by the cell itself, and the class II MHC pathway is centered on materials acquired from outside the antigen-presenting cell. This distinction, however, is by no means absolute. Together, the class I and class II pathways of antigen processing and presentation sample all of the compartments that need to be surveyed for the presence of pathogens.

Antigen processing and presentation in both the class I and II pathways may be divided into six discrete steps that are useful in comparing the two pathways: (1) acquisition of antigen, (2) tagging the antigen for destruction, (3) proteolysis, (4) delivery of peptides to MHC molecules, (5) binding of peptide to a MHC molecule, and (6) display of the peptide-loaded MHC molecule on the cell surface. In the next two sections, we describe the molecular details of each pathway.

Class I MHC Pathway Presents Cytosolic Antigens

Figure 24-25 summarizes the six steps in the class I MHC pathway using a virus-infected cell as an example. The following discussion describes the events that occur during each step:

1 Acquisition of Antigen: In the case of a virus infection, acquisition of antigen is usually synonymous with the infected state. Viruses rely on host protein synthesis to generate the building blocks for new virions. This includes the synthesis of viral cytosolic proteins as well as membrane proteins. Protein synthesis, unlike DNA replication, is an error-prone process, with 10–30 percent of newly initiated polypeptide chains being terminated prematurely or suffering from errors (misincorporation of amino acids, frame shifts, improper or delayed folding). These mistakes in protein synthesis affect both the host cell’s own proteins and those specified by viral genomes. Such error-containing proteins must be rapidly removed so as not to clog up the

▲ **FIGURE 24-25 Class I MHC pathway of antigen processing and presentation.** Step **1**: Acquisition of antigen is synonymous with the production of proteins with errors (premature termination, misincorporation). Step **2**: Misfolded proteins are targeted for degradation through conjugation with ubiquitin. Step **3**: Proteolysis is carried out by the proteasome. In cells exposed to interferon γ , the catalytically active β subunits of the proteasome are replaced by

interferon-induced immune-specific β subunits. Step **4**: Peptides are delivered to the interior of the endoplasmic reticulum (ER) via the dimeric TAP peptide transporter. Step **5**: Peptide is loaded onto newly made class I MHC molecules within the peptide-loading complex. Step **6**: The fully assembled class I MHC–peptide complex is transported to the cell surface via the secretory pathway. See text for details.

cytoplasm or engage partner proteins in nonproductive interactions. The rate of cytosolic proteolysis must be matched to the rate at which mistakes in protein synthesis occur. These rapidly degraded proteins are an important source of antigen peptides destined for presentation by class I MHC molecules. With the exception of cross-presentation (discussed below), the class I MHC pathway results in the formation of peptide-MHC complexes in which the peptides are derived from proteins synthesized by the class I MHC-bearing cell itself.

2 *Tagging the Antigen for Destruction:* For the most part, the ubiquitin conjugation system is responsible for tagging a protein for destruction (see Chapter 3, p. 88). Ubiquitin conjugation is tightly regulated.

3 *Proteolysis:* Ubiquitin-conjugated proteins are destroyed by proteasomal proteolysis. The proteasome is a highly processive protease that engages its substrates and, without the release of intermediates, yields final digestion products, peptides in the size range of 3–20 amino acids (see Figure 3-29). During the course of an inflammatory response and in response to interferon γ , the three catalytically active β subunits ($\beta 1$, $\beta 2$, $\beta 5$) of the proteasome can be replaced by three immune-specific subunits: $\beta 1i$, $\beta 2i$ and $\beta 5i$. The $\beta 1i$, $\beta 2i$ and $\beta 5i$ subunits are encoded in the MHC. The net result of this replacement is the generation of the *immunoproteasome*, the output of which is matched to the requirements for peptide binding by class I MHC molecules. The immunoproteasome adjusts the average length of the peptides produced, as well

as the sites at which cleavage occurs. Given the central role of the proteasome in the generation of peptides presented by class I MHC molecules, proteasome inhibitors potentially interfere with antigen processing via the class I MHC pathway.

4 *Delivery of Peptides to Class I Molecules:* Protein synthesis, ubiquitin conjugation, and proteasomal proteolysis all occur in the cytoplasm, whereas peptide binding by class I MHC molecules occurs in the lumen of the endoplasmic reticulum (ER). Thus peptides must cross the ER membrane to gain access to class I molecules, a process mediated by the heterodimeric TAP complex, a member of the **ABC superfamily** of ATP-powered pumps (see Figure 11-14). The TAP complex binds peptides on the cytoplasmic face and, in a cycle that includes ATP binding and hydrolysis, peptides are translocated into the ER. The specificity of the TAP complex is such that it can transport only a subset of all cytosolic peptides, primarily those in the length range of 5–10 amino acids. The mouse TAP complex shows a pronounced preference for peptides that terminate in leucine, valine, isoleucine, or methionine residues, which match the binding preference of the class I MHC molecules served by the TAP complex. The genes encoding the TAP1 and TAP2 subunits composing the TAP complex are located in the MHC.

5 *Binding of Peptides to Class I Molecules:* Within the ER, newly synthesized class I MHC molecules are part of a multiprotein complex referred to as the peptide-loading complex. This complex includes two chaperones (calnexin and calreticulin) and the oxidoreductase Erp57. Another chaperone (tapasin) interacts with both the TAP complex and the class I MHC molecule about to receive peptide. The physical proximity of TAP and the class I MHC molecule is maintained by tapasin. Once peptide loading has occurred, a conformational change releases the loaded class I MHC molecule from the peptide-loading complex.

6 *Display of Class I MHC–Peptide Complexes at the Cell Surface:* Once peptide loading is complete, the class I MHC–peptide complex is released from the peptide-loading complex and enters the constitutive secretory pathway (see Figure 14-1). Class I MHC molecules, depending on the species and allelic identity, contain between one and three N-linked oligosaccharides, which receive extensive modifications in the Golgi complex. Transfer from the Golgi to the cell surface is rapid and completes the biosynthetic pathway of a class I MHC–peptide complex.

The entire sequence of events in the class I pathway occurs constitutively in all nucleated cells, which express class I MHC molecules and the other required proteins or can be induced to do so. In the absence of a virus infection, protein synthesis and proteolysis continuously generate a stream of peptides that are loaded onto class I MHC molecules. Healthy, normal cells therefore display on their surface a representative selection of peptides derived from

host proteins. There may be several thousand distinct MHC–peptide combinations displayed at the surface of a typical class I MHC positive cell. Developing T cells in the thymus calibrate their antigen-specific receptors on these sets of MHC–peptide complexes, and learn to recognize self-MHC products as the “restriction elements” on which they must henceforth rely for antigen recognition. At the same time, the display of self-peptides by self-MHC molecules enables the developing T cell to learn which peptide-MHC combinations are self-derived and must therefore be ignored to avoid a self-destructive autoimmune reaction. It is not until a virus makes its appearance that virus-derived peptides begin to make a contribution to the display of peptide-MHC complexes. The overall efficiency of this pathway is such that approximately 4000 molecules of a given protein must be destroyed to generate a single MHC–peptide complex carrying a peptide from that particular polypeptide.

An unusual mode of antigen presentation that is nonetheless crucial in the development of cytotoxic T cells is *cross-presentation*. This term refers to the acquisition by dendritic cells of apoptotic cell remnants, immune complexes, and possibly other forms of antigen by phagocytosis. By a pathway that has yet to be understood, these materials escape from phagosomal/endosomal compartments into the cytosol, where they are then handled according to the steps described above. Only dendritic cells are capable of cross-presentation, and so allow the loading of class I MHC molecules complexed with peptides that derive from cells other than the antigen-presenting cell itself.

Class II MHC Pathway Presents Antigens Delivered to the Endocytic Pathway

Although class I MHC and class II MHC molecules show a striking structural resemblance, the manner in which the two classes acquire peptide and their function in immune recognition differ greatly. Whereas the primary function of class I MHC molecules is to guide CD8-bearing cytotoxic T cells to their target cells, class II MHC molecules serve to guide CD4-bearing helper T cells to the cells with which they interact, primarily professional antigen-presenting cells.

As noted previously, class II MHC molecules are expressed primarily by professional antigen-presenting cells: dendritic cells and macrophages, which are phagocytic, and B cells, which are not. Hence, the class II MHC pathway of antigen processing and presentation generally occurs only in these cells. The steps in this pathway are depicted in Figure 24-26 and described below:

1 *Acquisition of Antigen:* In the class II MHC pathway, antigen is acquired by pinocytosis, phagocytosis, or receptor-mediated endocytosis. Pinocytosis, which is rather non-specific, involves the delivery, by a process of membrane invagination and fission, of a volume of extracellular fluid and the molecules dissolved therein. **Phagocytosis**, the

▲ FIGURE 24-26 Class II MHC pathway of antigen processing and presentation. Step **1**: Particulate antigens are acquired by phagocytosis, and nonparticulate antigens by pinocytosis or endocytosis. Step **2**: Exposure of antigen to the low pH and reducing environment of endosomes and lysosomes prepares the antigen for proteolysis. Step **3**: The antigen is broken down by various proteases in endosomal and lysosomal compartments. Step **4**: Class II MHC molecules, assembled in the ER from their subunits, are delivered to

endosomal/lysosomal compartments by means of signals contained in the associated invariant (Ii) chain. This delivery targets late endosomes, lysosomes, and early endosomes, ensuring that class II MHC molecules are exposed to the products of proteolytic breakdown of antigen along the entire endocytic pathway. Step **5**: Peptide loading is accomplished with the assistance of DM, a class II MHC-like chaperone protein. Step **6**: Display of peptide loaded Class II MHC molecules at the cell surface. See text for details.

ingestion of particulate materials, such as bacteria, viruses, and remnants of dead cells, involves extensive remodeling of the actin-based cytoskeleton to accommodate the incoming particle. Although phagocytosis may be initiated by specific receptor-ligand interactions, these are not always required: Even latex particles can be ingested very efficiently by macrophages. In the process of opsonization, pathogens decorated by antibodies and certain complement components are targeted to macrophages and dendritic

cells, recognized by cell-surface receptors for complement components or the Fc portion of immunoglobulins, and then phagocytosed (Figure 24-27). Macrophages and dendritic cells also express several types of nonspecific receptors (e.g., Toll-like receptors, scavenger receptors) that recognize molecular patterns on nonparticulate antigens; the bound antigen is internalized by **receptor-mediated endocytosis**. B cells, which are not phagocytic, also can acquire antigen by receptor-mediated endocytosis using their

▲ FIGURE 24-27 Presentation of opsonized antigen by phagocytic cells. By means of Fc receptors such as Fc γ R displayed on their cell surface, specialized phagocytic cells such as macrophages or dendritic cells can bind and ingest pathogens that have been decorated with antibodies (opsonization). After digestion of the phagocytosed particle (e.g., immune complex, bacterium, virus), some of the peptides produced, including fragments of the pathogen (orange) are loaded onto class II MHC molecules. Class II MHC–peptide complexes displayed at the surface allow activation of T cells specific for these MHC–peptide combinations. Lipid antigens are delivered to the class I MHC-like molecule CD1, whose binding site is specialized to accommodate lipids. Certain pathogen-derived peptides (purple) may be delivered to class I MHC products by means of cross-presentation. The mechanisms that underlie cross-presentation remain to be clarified.

▲ FIGURE 24-28 Antigen presentation by B cells. B cells bind antigen, even if present at low concentration, to their B cell receptors, or surface Ig. The immune complex that results is internalized and then delivered to endosomal/lysosomal compartments where it is destroyed. Peptides liberated from the immune complex, including fragments of the protein antigen, are displayed as class II MHC–peptide complexes at the cell surface. CD4 T cells specific for the displayed complex can now provide help to the B cell. This help is MHC restricted and antigen specific.

antigen-specific B-cell receptors (surface immunoglobulin) (Figure 24-28). Finally, cytosolic antigens may enter the class II MHC pathway via autophagy (see Figure 14-35). After formation of the autophagic cup, an autophagic vesicle is formed. These vesicles are of a size that can accommodate damaged organelles, and sizable quantities of cytoplasm may be encapsulated in the process. The resulting autophagosomes are destined to fuse with lysosomes, where the contents of the autophagosome then become available for digestion by lysosomal proteases.

2 Tagging Antigen for Destruction: Proteolysis is required to convert intact protein antigen into peptides of a size suitable for binding to Class II MHC molecules. Protein antigens are tagged for degradation by progressive unfolding, brought about by the drop in pH as proteins progress along the endocytic pathway. The pH of the extracellular environment is around pH 7.2, and that in early endosomes

between pH 6.5 and 5.5; in late endosomes and lysosomes the pH may drop to pH 4.5. ATP-powered V-class proton pumps in the endosomal and lysosomal membranes are responsible for this acidification (see Figure 11-9). Proteins stable at neutral pH tend to unfold when exposed to extremes of pH, through rupture of hydrogen bonds and destabilization of salt bridges. Further, the environment in the endosomal/lysosomal compartments is reducing, with lysosomes attaining a concentration of reducing equivalents in the millimolar range. Reduction of disulfide bonds that stabilize many extracellular proteins is catalyzed also by a thioreductase inducible by exposure to IFN γ . The combined action of low pH and reducing environment prepares the antigens for proteolysis.

3 *Proteolysis:* Degradation of proteins in the class II MHC pathway is carried out by a large set of lysosomal proteases, collectively referred to as cathepsins, which are either cysteine or aspartyl proteases. Other proteases, such as asparagine-specific endoprotease, also may contribute to proteolysis. A wide range of peptide fragments is produced, including some that can bind to class II MHC molecules. The lysosomal proteases operate optimally at the acidic pH within lysosomes. Consequently, agents that inhibit the activity of V-class proton pumps interfere with antigen processing, as do inhibitors of lysosomal proteases.

4 *Delivery of Peptides to Class II Molecules:* Recall that most class II MHC molecules synthesized in the endoplasmic reticulum are directed to late endosomes. Because the peptides generated by proteolysis reside in the same topological space as the class II MHC molecules themselves, the delivery of peptide to class II MHC molecules does not require traversal of a membrane. The sole requirement, therefore, is to allow peptides and class II MHC molecules to meet. This is accomplished in the course of biosynthesis by a sorting step that is dependent on the invariant chain (Ii) and ensures delivery of the class II ($\alpha\beta$ Ii)₃ complex to endosomal compartments.

5 *Binding of Peptides to Class II Molecules:* The ($\alpha\beta$ Ii)₃ complex delivered to endosomal compartments is incapable of binding peptide because the peptide-binding cleft in the class II molecule is occupied by Ii. The same proteases that act on internalized antigens and degrade them into peptides act also on the ($\alpha\beta$ Ii)₃ complex, resulting in removal of Ii with the exception of a small portion called the CLIP segment. Because it is firmly lodged in the class II MHC peptide-binding cleft, CLIP is resistant to proteolytic attack. The class II MHC molecules themselves are also resistant to unfolding and proteolytic attack under the conditions that prevail in the endocytic pathway. The CLIP segment is removed through interaction of the $\alpha\beta$ CLIP complex with a chaperone, DM. Although the DM protein is MHC-encoded and structurally very similar to class II molecules, it is unable to bind peptides. Newly formed class II MHC-peptide complexes are themselves susceptible to further “editing” by DM, until the class II molecule acquires a peptide so stably bound that it cannot be dislodged by interaction of the

complex with DM. The resulting class II MHC-peptide complexes are extremely stable, with estimated half lives in excess of 24 hours.

6 *Display of Class II MHC–Peptide Complexes at the Cell Surface:* The newly generated class II MHC-peptide complexes are localized mostly in late endosomal compartments, which include multivesicular endosomes (or bodies) (see Figure 14-33). Recruitment of the internal vesicles of the multivesicular bodies to the delimiting membrane expands their surface area; by a process of tubulation along tracks of microtubules, these compartments elongate and ultimately deliver class II MHC-peptide complexes to the surface by membrane fusion. These events are tightly regulated: Tubulation and delivery of class II MHC molecules to the surface are enhanced in dendritic cells and macrophages following their activation in response to signals, such as bacterial lipopolysaccharide (LPS), which is detected by their Toll-like receptors.

For professional antigen-presenting cells, the above steps are constitutive—happening all the time—but they can be modulated by exposure to microbial agents and cytokines.

KEY CONCEPTS OF SECTION 24.4

The MHC and Antigen Presentation

- The MHC, discovered as the genetic region responsible for acceptance or rejection of grafts, encodes two major classes of type I membrane glycoproteins, class I and class II MHC molecules. These proteins are highly polymorphic, occurring in many allelic variations in an outbred population (see Figure 24-21).
- The function of MHC products is to bind peptides and display them to antigen-specific receptors on T cells. Class I MHC molecules are found on most nucleated cells, whereas the expression of class II MHC molecules is confined largely to professional antigen-presenting cells such as dendritic cells, macrophages, and B cells.
- The organization and structure of class I and class II MHC molecules is similar and includes a region specialized for binding a wide variety of different peptides (see Figure 24-23).
- Different allelic variants of MHC molecules bind different sets of peptides, because the differences that distinguish one allele from another include residues that define the architecture of the peptide-binding cleft (see Figure 24-24). Allelic residues also include residues contacted by the T-cell receptor for antigen. Thus different allelic variants of an MHC molecule, even if they were to bind the identical peptide, will not usually react with a T-cell receptor designed to interact with only one of the allelic MHC molecules. This phenomenon is called MHC restriction.
- Class I and class II MHC molecules sample different intracellular compartments for peptide: Class I molecules sample predominantly cytosolic materials, whereas class II molecules

sample extracellular materials internalized by phagocytosis, pinocytosis, or receptor-mediated endocytosis.

- The process by which protein antigens are acquired, processed into peptides and converted into surface-displayed MHC-peptide complexes is referred to as antigen processing and presentation. This process operates continuously in cells that express the relevant MHC molecules, yet can be modulated in the course of an immune response.
- Antigen processing and presentation can be divided into six discrete steps: (1) acquisition of antigen, (2) tagging the antigen for destruction; (3) proteolysis; (4) delivery of peptides to MHC molecules; (5) binding of peptide to the MHC molecule; and (6) display of the peptide-loaded MHC molecules on the cell surface (see Figures 24-25 and 24-26).

24.5 T Cells, T-Cell Receptors, and T-Cell Development

T lymphocytes recognize antigen through the lens of MHC molecules. The receptors entrusted with this task are structurally related to immunoglobulins. To generate these antigen-specific receptors, T cells rearrange the genes encoding the T-cell receptor (TCR) subunits by mechanisms of somatic recombination identical to those used by B cells to rearrange immunoglobulin genes. The development of T cells is also strictly dependent on successful completion of the somatic gene rearrangements that yield the TCR subunits. We shall describe the subunits that mediate antigen-specific recognition, how they pair up with membrane glycoproteins essential for signal transduction, and how these complexes recognize MHC-peptide combinations.

As pointed out in the preceding section, T cells recognize antigens only together with the polymorphic MHC molecules that happen to be present in that host. In the course of T cell development, T cells must “learn” the identity of these self-MHC molecules and receive instructions about which MHC-peptide combinations to ignore, so as to avoid potentially catastrophic reactivity of newly generated T cells with the host’s own tissues (i.e., autoimmunity). We shall describe how T cells develop and introduce the major classes of T cells according to their function.

The Structure of the T-Cell Receptor Resembles the F(ab) Portion of an Immunoglobulin

Much as B cells utilize the B-cell receptor to recognize antigen and then transduce signals that lead to their clonal expansion, so T cells use their T-cell receptors. T cells that have been activated through engagement of these antigen-specific receptors proliferate and acquire the capacity to kill antigen-bearing target cells or to secrete cytokines that will assist B cells in their differentiation. The T-cell receptor for antigen

recognizes MHC molecules complexed with the appropriate peptides.

The structure of the T-cell receptor was elucidated based on two assumptions. The first was the notion that the variability of T-cell receptors, given their ability to distinguish between closely related antigens, would be considerable. On the assumption that each T cell possesses a clonally distributed antigen-specific receptor, it should be possible to raise antibodies against the features unique to a T-cell receptor expressed by a particular T-cell clone (clonotypic antibodies). Such antibodies should react uniquely with cells from the same clone that served as the source of the T cell receptor and not with other T cells. Such antibodies were used successfully to arrive at a first description of the T-cell receptor. A second assumption was the need for somatic rearrangement to generate the requisite number of antigen-specific T-cell receptors. cDNA clones encoding the putative TCR subunits, when used as probes, should reveal whether somatic rearrangement does in fact occur. A comparison of the organization of a TCR locus in germ-line configuration and in mature T cells should show evidence of somatic rearrangement.

The immunochemical approach, through use of clonotypic antibodies and other T cell-specific monoclonal antibodies, yielded the structure of the T-cell receptor (Figure 24-29). It is composed of two glycoprotein subunits, each of which is encoded by a somatically rearranged gene. The receptors are composed of either an $\alpha\beta$ pair, or a $\gamma\delta$ pair. The structure of these subunits shows structural similarity to the F(ab) portion of an immunoglobulin: at the N-terminal end there is a variable domain, followed by a constant-region domain and a transmembrane segment. The cytoplasmic tails of the TCR subunits are too short to allow recruitment of cytosolic factors that assist in signal transduction. Instead, the TCR associates with the CD3 complex, a set of membrane proteins composed of γ , δ , ϵ , and ζ chains. (The TCR γ and δ subunits are not to be confused with the similarly designated subunits of the CD3 complex.) The ϵ chain forms a noncovalent dimer with the γ on the δ chain to yield $\delta\epsilon$ and $\gamma\epsilon$ complexes. The external domain of the CD3 subunits is homologous to immunoglobulin domains, and the cytoplasmic domain in each contains an ITAM domain, through which adapter molecules may be recruited upon phosphorylation of tyrosine residues in the ITAMs. The ζ chain is integrated into the CD3-TCR complex as a disulfide-bonded homodimer, and each ζ chain contains three ITAM motifs.

TCR Genes Are Rearranged in a Manner Similar to Immunoglobulin Genes

Virtually all antigen-specific receptors generated by somatic recombination contain a subunit that is the product of V-D-J recombination (e.g., Ig heavy chain; TCR β chain) and a subunit produced by V-J recombination (e.g., Ig light chain; TCR α chain). The mechanism of V-D-J and V-J recombination

◀ **FIGURE 24-29 Structure of the T-cell receptor and its co-receptors.** (a) The T-cell receptor (TCR) for antigen is composed of two chains, the α and β subunits, which are produced by V-J and V-D-J recombination, respectively. The $\alpha\beta$ subunits must associate with the CD3 complex (see Figure 24-31) to allow the transduction of signals. The formation of a full TCR $\alpha\beta$ -CD3 complex is required for surface expression. The T-cell receptor further associates with the co-receptors CD8 (light blue) and CD4 (light green), which allow interaction with conserved features of class I MHC and class II MHC molecules, respectively, on antigen-presenting cells. (b) Structure of the T-cell receptor bound to a class II MHC-peptide complex as determined by x-ray crystallography. [Part (b) based on J. Hennecke, 2000, *E MBO* **19**: 5611.]

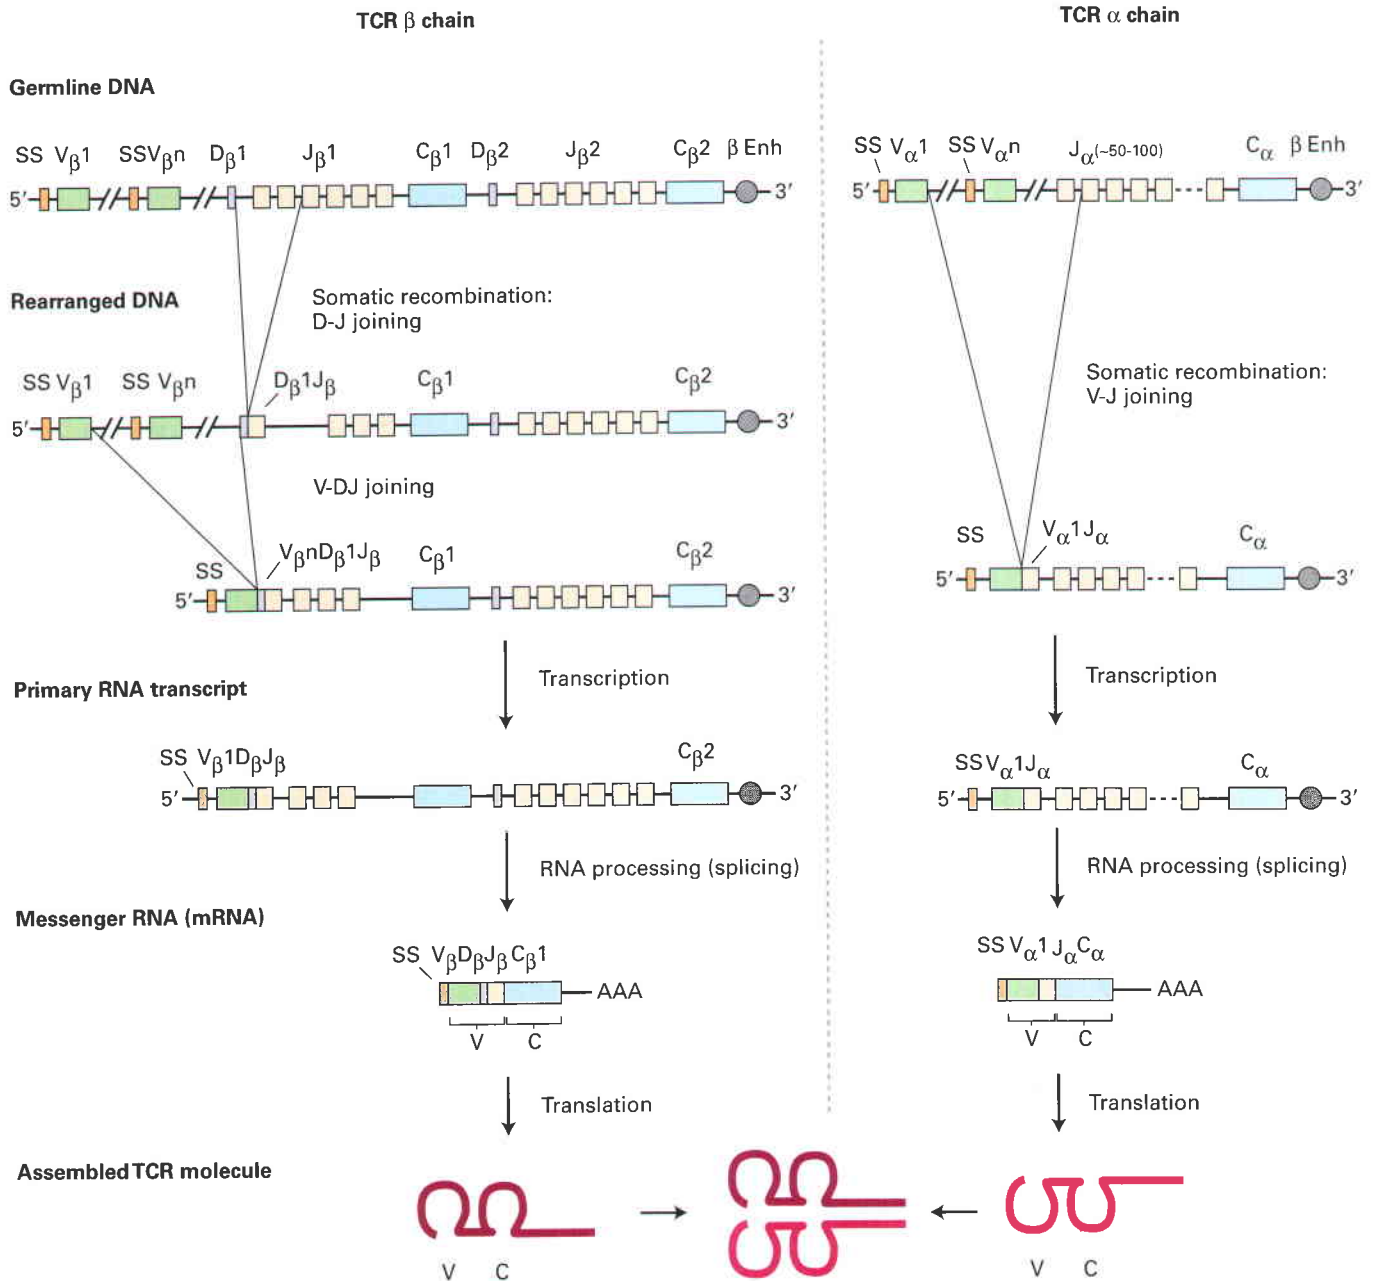

for the TCR loci is identical to that described for immunoglobulin genes, and requires all the component proteins composing the nonhomologous end-joining machinery: RAG-1, RAG-2, Ku70, Ku80, DNA-PK catalytic subunit, XRCC4, DNA ligase IV, and Artemis. There is an absolute requirement for the recombination signal sequences (RSSs), and recombination obeys the 12/23 bp spacer rule (Figure 24-30).

A number of noteworthy features characterize the organization and rearrangement of the TCR loci. First, the organization of the recombination signals is such that D-to-D rearrangements are allowed. Second, the enzyme terminal deoxynucleotidyltransferase (TdT) is active at the time the TCR genes rearrange, and therefore N nucleotides can be present in all rearranged TCR genes. Third, in the human and mouse, the TCR δ locus is embedded within the TCR α locus. This organization results in complete excision of the interposed δ locus, and so a choice of the TCR α locus for rearrangement precludes utilization of the δ locus, now lost by deletion. T cells that express the $\alpha\beta$ receptor and those that express the $\gamma\delta$ receptor are considered separate lineages with distinct functions. Among the T cells expressing $\gamma\delta$ receptors are some capable of recognizing the CD1 molecule, which is specialized in the presentation of lipid antigens. The $\gamma\delta$ T cells are programmed to hone in on distinct anatomical sites (e.g., the epithelium lining the genital tract, the skin) and likely play a role in host defense against pathogens commonly found at these sites.

Deficiencies in the key components of the recombination apparatus, such as the RAG recombinases, preclude rearrangement of TCR genes. As we have seen for B cells, and as will be described below for T cells, development of lymphocytes is strictly dependent on the rearrangement of the antigen-receptor genes. A RAG deficiency thus prevents both B- and T-cell development.

T-Cell Receptors Are Very Diverse with Many of Their Variable Residues Encoded in the Junctions between V, D, and J Gene Segments

The diversity created by somatic rearrangement of TCR genes is enormous, estimated to exceed 10^{10} unique receptors.

▲ FIGURE 24-30 Organization and recombination of TCR loci. The organization of TCR loci is in principle similar to that of immunoglobulin loci (see Figure 24-14). (Left) The TCR β -chain locus includes a cluster of V segments, a cluster of D segments, and several J segments, downstream of which are two constant regions. The

arrangement of the recombination signals is such that not only is D-J joining allowed, but also V-DJ joining. Direct V-J joining in the TCR β locus is not observed. (Right) The TCR α -chain locus is composed of a cluster of V segments and a large number of J segments. SS = exon encoding signal sequence; Enh = enhancer.

Combinatorial usage of different V, D, and J gene segments makes an important contribution, as do the mechanisms of junctional imprecision and N-nucleotide addition already discussed. The net result is a degree of variability in the V regions that matches that of the CDR3 of immunoglobulins (see Figure 24-12). Unlike immunoglobulin genes, the TCR genes do not undergo somatic hypermutation, and thus T-cell receptors exhibit nothing equivalent to the affinity maturation of antibodies during the course of an immune response.

The crystal structures of a number of T-cell receptors bound to class I MHC-peptide or class II MHC-peptide complexes have been solved. These structures show variability in how the T-cell receptor docks with the MHC-peptide complex, but the most extensive contacts in the CDR3 region are made with the central peptide portion of the complex, with CDR1 and CDR2 contacting the α helices of the MHC molecules. Many of the T-cell receptors for which a structure has been solved sit down diagonally

across the peptide-binding portion of the MHC-peptide complex. As a result, the T-cell receptor makes extensive contacts with the peptide cargo as well as with the α helices of the MHC molecule to which it binds. The positions at which allelic MHC molecules differ from one another frequently involve residues that directly contact the T-cell receptor, thus precluding tight binding of the “wrong” allele.

Amino acid differences that distinguish one MHC allele from another also affect the architecture of the peptide-binding cleft. Even if the MHC residues that interact directly with the T-cell receptor were shared by two MHC allelic molecules, their peptide-binding specificity is likely to differ because of amino acid differences in the peptide-binding cleft. Consequently, the TCR contact residues provided by bound peptide and essential for stable interaction with a T-cell receptor would be absent from the “wrong” MHC-peptide combination. A productive interaction with the T cell receptor is then unlikely to occur.

Signaling via Antigen-Specific Receptors Triggers Proliferation and Differentiation of T and B Cells

Both B-cell and T-cell receptors for antigen transduce signals by means of proteins associated with the antigen-specific portions of the receptor (i.e., Ig heavy and light chains for the BCR; α and β chains for the TCR). The cytosolic portions of the antigen-specific receptors themselves are very short, do not protrude much beyond the cytosolic leaflet of the plasma membrane, and are incapable of recruitment of downstream signaling molecules. Instead, as discussed previously, the antigen-specific receptors on T and B cells associate with auxiliary subunits that contain ITAMs (immunoreceptor tyrosine based activation motifs). Engagement of antigen-specific receptors by ligand initiates a series of receptor-proximal events: kinase activation, modification of ITAMs, and subsequent recruitment of adapter molecules that serve as scaffolds for recruitment of yet other downstream signaling molecules.

As outlined in Figure 24-31, engagement of antigen-specific receptors activates Src family tyrosine kinases (e.g., Lck in CD4 T cells; Lyn and Fyn in B cells). These kinases are found in close proximity to or physically associated with the antigen receptor. The active Src kinases phosphorylate the ITAMs in the antigen receptors' auxiliary subunits. In their phosphorylated forms, these ITAMs recruit and activate non-Src family tyrosine kinases (ZAP-70 in T cells, Syk in B cells) as well as other adapter molecules. Such recruitment and activation involves phosphoinositide-specific phospholipase C_{γ} and PI-3 kinases. Subsequent downstream events parallel those discussed in Chapter 16 for signaling from receptor tyrosine kinases. Ultimately signaling via antigen-specific receptors initiates transcription programs that determine the fate of the activated lymphocyte: proliferation and differentiation.

T cells depend critically on the cytokine interleukin 2 (IL-2) for clonal expansion. Following antigen stimulation of a T cell, one of the first genes to be turned on is that for IL-2. The T cell responds to its own initial burst of IL-2 and proceeds to make more IL-2, an example of autocrine stimulation and part of a positive feedback loop. An important transcription factor required for the induction of IL-2 synthesis is the NF-AT protein (nuclear factor of activated T cells). This protein is sequestered in the cytoplasm in phosphorylated form and cannot enter the nucleus unless it is dephosphorylated first. The phosphatase responsible is calcineurin, a Ca^{2+} -activated enzyme. The rise in cytosolic Ca^{2+} leading to activation of calcineurin results from mobilization of ER-resident Ca^{2+} stores triggered by hydrolysis of PIP_2 and the concomitant generation of IP_3 (see Figure 15-30, steps 2–4).

The immunosuppressant drug cyclosporine inhibits calcineurin activity through formation of a cyclosporine-cyclophilin complex, which binds and inhibits calcineurin. If dephosphorylation of NF-AT is suppressed, NF-AT cannot enter the nucleus and participate in the up-regulation of transcription of the IL-2 gene. This precludes expansion of antigen-stimulated T cells and so leads to immunosuppression, arguably the single most important intervention that contributes to successful organ transplantation. Although the success of transplantation varies with the organ used, the availability of strong immunosuppressants such as cyclosporine has expanded enormously the possibilities of clinical transplantation. ■

T Cells Capable of Recognizing MHC Molecules Develop Through a Process of Positive and Negative Selection

The rearrangement of the gene segments that are assembled into a functional T-cell receptor is a stochastic event, completed on the part of the T cell without any prior knowledge of the MHC molecules with which these T-cell receptors must ultimately interact. Similar to somatic recombination of Ig heavy-chain loci in B cells, the first TCR gene segments to rearrange are the TCR β D and J elements, followed by joining of a V segment to the newly recombined DJ. At this stage of T-cell development, productive rearrangement allows the synthesis of the TCR β chain, which is incorporated into the pre-TCR through association with the pre-T α subunit. This pre-TCR fulfills a function strictly analogous to that of the pre-BCR in B-cell development: It allows expansion of pre-T cells that successfully underwent rearrangement, and it imposes allelic exclusion to ensure that, as a rule, a single functional TCR β subunit is generated for a given T cell and its descendants. After the expansion phase of pre-T cells is complete, rearrangement of the TCR α locus is initiated, ultimately leading to the generation of T cells with a fully assembled TCR $\alpha\beta$ receptor.

▲ **FIGURE 24-32 Comparison of T-cell and B-cell development.** Cell fate decisions are executed by receptors composed of either the newly rearranged μ chain (pre-BCR) or the newly rearranged β chain (pre-TCR). The pre-B and pre-T cell receptors serve similar functions: expansion of cells that successfully underwent rearrangement and allelic exclusion. This phase of lymphocyte development does not require antigen-specific recognition. Both the pre-BCR and pre-TCR include subunits unique to each receptor and absent from the antigen-specific receptors found on mature lymphocytes: V_{preB} and

$\lambda 5$ (orange, green) for the pre-BCR; pre-T α (blue) for the pre-TCR. Upon completion of the expansion phase, expression begins of the gene encoding the remaining subunit of the antigen-specific receptor: Ig light chain (light blue) for the BCR; TCR α chain (light red) for the TCR. Lymphocyte development and differentiation occur at distinct anatomical sites, and only fully assembled antigen-specific receptors (BCR, TCR) recognize antigen. Mature lymphocytes are strictly dependent on antigen recognition for their activation.

Figure 24-32 illustrates the analogous steps in the development of T and B cells.

How is the newly emerging repertoire of T cells shaped so that a productive interaction with self-MHC molecules can occur? The random nature of the gene rearrangement process and the enormous variability engendered as a consequence produces a set of T-cell receptors, the vast majority of which cannot productively interact with the host MHC products. Recall that antigen processing and presentation are constitutive processes, and that in the thymus, where these selection events take place, all self-MHC molecules are necessarily occupied with peptides derived from self-proteins. These combinations of self-peptides complexed to class I and class II MHC molecules constitute the template on which the initial set of T-cell receptors must be calibrated.

T cells born with receptors that cannot engage self-MHC are useless. Such T cells will fail to perceive survival signals via the newly generated T-cell receptors and die. At the other

extreme are T cells endowed with receptors that show a perfect fit for self-MHC complexed with a particular self-peptide. These T cells, if allowed to leave the thymus and take up residence in peripheral lymphoid organs, would be by definition self-reactive and could cause autoimmunity. If the number of such self-peptide MHC combinations surpasses a threshold sufficient to allow triggering of the T-cell receptor, then these T cells are instructed to die by apoptosis. This is called negative selection and serves to purge the T-cell repertoire of overtly self-reactive T cells. Any T cell equipped with a receptor that perceives signals sufficiently strong to allow survival, but below the threshold that would impel the T cell to initiate apoptosis, is positively selected. The heterogeneity of peptide-MHC complexes displayed on the surface of T cells undergoing selection makes it highly probable that the T-cell receptor interprets signals in additive fashion: The summation of binding energies of the different MHC-self-peptide combinations on display determine the outcome of selection. This is called the *avidity model of T-cell selection*.

T cells are killed off by apoptosis only if the appropriate self-antigen is represented adequately in the thymus as MHC-peptide complexes. Proteins that are expressed in tissue-specific fashion, such as insulin in the β cells of the pancreas or the components of the myelin sheath in the nervous system, do not obviously fit this category. However, a factor called AIRE (autoimmune regulator) allows expression in a subset of epithelial cells of such tissue-specific antigens. How AIRE accomplishes this is not known, but it is widely suspected of directly regulating the transcription of the relevant genes. Defects in AIRE lead to a failure to express these

◀ **FIGURE 24-33 Signals involved in T-cell activation and termination.** The two-signal model of T-cell activation involves recognition of an MHC-peptide complex by the T-cell receptor, which constitutes Signal 1 (1), along with recognition of costimulatory molecules (CD80, CD86) on the surface of the antigen-presenting cell, which constitutes Signal 2 (2). If costimulation is not provided, the newly engaged T cell becomes unresponsive (anergic). The provision of both Signal 1 via the T-cell receptor and Signal 2 via engagement of CD80 and CD86 by CD28 allows full activation. Full activation, in turn, leads to increased expression of CTLA4 (3). After moving to the T-cell surface, CTLA4 binds CD80 and CD86, leading to inhibition of the T-cell response (4). Because the affinity of CTLA4 for CD80 and CD86 is greater than that of the CD28, T-cell activation eventually is terminated.

tissue-specific antigens in the thymus. In individuals who do not express AIRE, developing T cells fail to receive the full set of instructions in the thymus that lead to elimination of potentially self-reactive T cells. As a consequence, these individuals show a bewildering array of autoimmune responses, causing widespread tissue damage and disease.

TCR rearrangement occurs coincident with the gradual acquisition of the co-receptors CD4 and CD8. A key intermediate in T-cell development is a thymocyte that expresses CD4 and CD8, as well as a functional TCR-CD3 complex. These cells are called double positive (CD4CD8⁺) cells and are found only as developmental intermediates in the thymus. The choice of which co-receptor (CD4 or CD8) to express determines whether a T cell will recognize class I or class II MHC molecules. How a newborn CD4CD8⁺ cell is instructed to become a CD8 (class I MHC restricted) T cell or CD4 (class II MHC restricted) T cell is not entirely settled.

T Cells Require Two Types of Signal for Full Activation

All T cells require a signal via their antigen-specific receptor, the TCR, for activation, but this is not sufficient: the T cell further needs costimulatory signals. To perceive costimulatory signals, T cells carry on their surface several different receptors, of which the CD28 molecule is the best-known example. CD28 interacts with CD80 and CD86 on the antigen-presenting cells with which the T cell interacts. Their expression is up-regulated when these antigen-presenting cells have themselves received the proper stimulatory signals, for example by engagement of their Toll-like receptors (TLRs). The signals delivered via CD28 synergize with signals that emanate from the engaged T-cell receptor, all of which are required for full activation (Figure 24-33).

T cells, once activated, also express receptors that provide an attenuating or inhibitory signal upon recognition of these very same costimulatory molecules. The CTLA4 protein, whose expression on T cells is induced only upon activation, competes with CD28 for binding of CD80 and CD86. Because the affinity of CTLA4 for the CD80 and CD86 proteins is higher than that of CD28, the inhibitory signals provided through CTLA4 will ultimately dominate the stimulatory

signals that derive from engagement of CD28. Costimulatory molecules can thus be stimulatory or inhibitory and provide an important means of controlling the activation status and duration of a T-cell response.

Cytotoxic T Cells Carry the CD8 Co-receptor and Are Specialized for Killing

As we've seen, cytotoxic T cells, also called cytolytic T lymphocytes (CTLs), generally carry the CD8 glycoprotein marker and are restricted in their recognition by class I MHC molecules. They kill target cells that display the appropriate MHC-peptide combinations and do so with exquisite sensitivity: A single MHC-peptide complex suffices to allow a properly primed CD8 T cell to kill the target cell that bears it.

The mechanism of killing by CTLs involves two classes of proteins that act synergistically, *perforins* and *granzymes* (Figure 24-34). Perforins, which exhibit homology to the terminal components of the complement cascade composing the membrane attack complex, form pores of up to 20 nm in membranes to which they attach. The destruction of an

intact permeability barrier, which leads to loss of electrolytes and other small solutes, contributes to cell death. Granzymes are delivered to and are presumed to enter the target cell, likely via the pores generated by perforin. Granzymes are serine proteases that activate effector caspases and so propel the target on a path of programmed cell death (apoptosis). Perforins and granzymes are packaged into cytotoxic granules, stored inside the cytotoxic T cell. Upon binding of the T-cell receptor to antigen, the cytotoxic granules and their contents are released into the cleft formed between the cytotoxic T cell and target cell. How the T cell avoids being killed upon release of granzymes and perforins into this synaptic cleft is still not known. Natural killer cells also exert cytotoxic activity and likewise rely on perforins and granzymes to kill their targets (see Figure 24-5).

T Cells Produce an Array of Cytokines That Provide Signals to Other Immune Cells

Many lymphocytes and nonlymphoid cells in lymphoid tissue produce cytokines. These small secreted proteins instruct lymphocytes what to do by binding to specific receptors on

▲ **FIGURE 24-34 Perforin- and granzyme-mediated cell killing by cytotoxic T cells.** Upon recognition of the target cell (1), cytotoxic T cells form tight antigen-specific contacts with target cells. Tight contact results in the formation of a synaptic cleft, into which the contents of cytotoxic granules are released (2). The content of these granules includes perforins and granzymes. Perforins form pores in the membranes onto which they adsorb, and granzymes are

serine proteases that enter through the perforin pores (3). Perforins are believed to act not only at the surface of the target cells, but also at the surface of endosomal compartments of target cells after the perforin molecules have been internalized from the cell surface (4). Once in the cytoplasm, the granzymes activate caspases, which initiate programmed cell death (5).

the lymphocyte surface and initiating a transcriptional program that allows the lymphocyte to either proliferate or differentiate into an effector cell ready to exert cytotoxic activity (CD8 T cells), helper activity (CD4 T cells), or antibody-secreting activity (B cells). Cytokines that are produced by or act primarily on leukocytes are called **interleukins**; at least 27 interleukins have been identified and molecularly characterized. Structurally related interleukins are recognized by cognate receptors with structural similarities, the interleukin-2 receptor being a particularly well-characterized example. Interleukin 2 (IL-2) was identified as T-cell growth factor and is one of the first cytokines produced when T cells are stimulated. IL-2 acts as an autocrine (self-acting) growth factor and drives clonal expansion of activated T cells.

Interleukin 4 (IL-4), which is produced by CD4 T cells specialized in providing help to B cells (discussed below) induces activated B cells to proliferate and to undergo class switch recombination and somatic hypermutation. Interleukin 7 (IL-7), produced by stromal cells in the bone marrow, is essential for development of T and B cells from committed precursors. Both IL-7 and IL-15 play a role in the maintenance of T cells in the form of *memory cells*, which are antigen-experienced cells that may be called upon when re-exposure to antigen occurs. These memory T cells then rapidly proliferate and deal with the intruder.

The mechanism of signal transduction by cytokine receptors through the JAK/STAT pathway is described in Chapter 16 (see Figure 16-1b for quick review). Among the many genes under the control of the STAT pathway are suppressors of cytokine signaling, or SOCS proteins. These proteins are themselves induced by cytokines, bind to the activated form of JAKs, and target them for proteasomal degradation (see Figure 16-14b).

CD4 T Cells Are Divided into Three Major Classes Based on Their Cytokine Production and Expression of Surface Markers

The major function of CD4 T cells is to provide assistance to B cells and guide their differentiation into plasma cells that secrete high-affinity antibodies. This function, carried out by helper T cells, requires both the production and secretion of cytokines, as well as direct contact between the CD4 T cell and the B cell to which it provides help.

A second type of CD4 T cell has as its major function secreting the cytokines that contribute to the establishment of an inflammatory environment. Multiple types of CD4 T cells have thus been defined based on the cytokines they produce and their functional properties. Whereas all activated T cells can produce IL-2, other cytokines are produced by particular CD4 T cell subsets. These CD4 T cells are classified as T_H1 cells, characterized by the production of interferon γ and TNF, and T_H2 cells, characterized by the production of IL-4 and IL-10. T_H1 cells, through production of IFN γ , can activate macrophages and stimulate an inflammatory response. Referred to also as *inflammatory T cells*, T_H1 cells nonetheless play an important role in antibody production, notably facilitating the production of

complement-fixing antibodies such as IgG1 and IgG3. T_H2 cells, through production of IL-4, play an important role in B-cell responses that involve class switch recombination to the IgG1 and IgE isotypes (discussed below). The combination of cytokines produced by CD4 T cells, and the interaction between the CD40 protein induced on activated T cells with CD40 ligand (CD40L) on B cells is responsible for induction of activation-induced deaminase, and so prepares the B cell for class switch recombination and somatic hypermutation.

A recently discovered subset of CD4 T cells are called *regulatory T cells*. They can attenuate immune responses by exerting a suppressive effect on cytokine production by other T cells. These regulatory T cells restrain the activity of potentially self-reactive T cells and are important in maintaining tolerance (the absence of an immune response to self antigens).

Leukocytes Move in Response to Chemotactic Cues Provided by Chemokines

Interleukins tell lymphocytes what to do by eliciting a transcriptional program that allows lymphocytes to acquire specialized effector functions. On the other hand, chemokines tell leukocytes where to go. Many cells emit chemotactic cues in the form of chemokines. When tissue damage occurs, resident fibroblasts produce a chemokine, IL-8, that attracts neutrophils to the site of damage. The regulation of lymphocyte trafficking within lymph nodes is essential for dendritic cells to attract T cells, and for T cells and B cells to meet. These trafficking steps are all controlled by chemokines.

There are approximately 40 distinct chemokines and more than a dozen chemokine receptors. One chemokine may bind to more than one receptor, and a single receptor can bind several different chemokines. This creates the possibility of generating a combinatorial code of chemotactic cues of great complexity. This code is used to allow the navigation of leukocytes from where they are generated, in the bone marrow, into the bloodstream for transport to their target destination.

Some chemokines direct lymphocytes to leave the circulation and take up residence in lymphoid organs. These migrations contribute to the population of lymphoid organs with the required sets of lymphocytes. Because these movements occur as part of normal lymphoid development, such chemokines are also referred to as *homeostatic chemokines*. Those chemokines that serve the purpose of recruiting leukocytes to sites of inflammation and tissue damage are referred to as *inflammatory chemokines*.

Chemokine receptors are G protein-coupled receptors that function as an essential step in the regulation of cell adhesion and cell migration. Leukocytes that travel through blood vessels do so at high speed and are exposed to high hydrodynamic shear forces. For a leukocyte to traverse the endothelium and take up residence in a lymph node or seek out a site of infection in tissue, it must first slow down, a process that requires interactions of surface receptors called selectins with their ligands, which are mostly carbohydrate

in nature. If chemokines are found in proximity, adsorbed to the extracellular matrix, and if the leukocyte possesses a receptor for that chemokine, activation of the chemokine receptor elicits a signal that allows integrins carried by the leukocyte to undergo a conformational change. This change results in an increase in affinity of the integrin for its ligand and causes firm arrest of the leukocyte. The leukocyte may now exit the blood vessel by a process known as *extravasation* (see Figure 19-36).

KEY CONCEPTS OF SECTION 24.5

T Cells, T-Cell Receptors, and T-Cell Development

- The antigen-specific T-cell receptors are dimeric proteins consisting of α and β subunits or γ and δ subunits. T cells occur in at least two major classes based on the expression of the glycoprotein co-receptors CD4 and CD8 (see Figure 24-29).
- Cells that use class I MHC molecules as restriction elements carry CD8; those that use class II MHC molecules carry CD4. These classes of T cells are functionally distinct: CD8 T cells are cytotoxic T cells; CD4 T cells provide help to B cells and are an important source of cytokines.
- Genes encoding the TCR subunits are generated by somatic recombination of V and J segments (α chain) and of V, D, and J segments (β chain); their rearrangement obeys the same rules as those defined for rearrangement of Ig genes in B cells (see Figure 24-30). Rearrangement of TCR genes occurs in the thymus and only in those cells destined to become T lymphocytes.
- A complete T-cell receptor includes the accessory CD3 complex, which is required for signal transduction. Each subunit of the CD3 complex carries in its cytoplasmic tail one or three ITAM domains; when phosphorylated, these ITAMs recruit accessory molecules involved in signal transduction (see Figure 24-31).
- In the course of T-cell development, the TCR β locus rearranges first, encoding a functional β subunit that is incorporated in the pre-TCR, which also includes a specialized pre-TCR α subunit encoded by an unrearranged gene (see Figure 24-32). Similar to the pre-BCR, the pre-TCR mediates allelic exclusion and proliferation of those cells that successfully underwent TCR β rearrangement.
- T cells destined to become CD8 T cells must interact with class I MHC molecules in the course of their development; those that will become CD4 T cells must interact with class II MHC molecules. Developing T cells that fail to recognize any MHC molecules at all die for lack of survival signals. T cells that interact too strongly with peptide-MHC complexes encountered during development are instructed to die (negative selection); those that have intermediate affinity for peptide-MHC complexes are allowed to mature (positive selection) and are exported from the thymus to the periphery.
- T cells are instructed where to go (cell migration) through chemotactic signals in the form of chemokines.

Receptors for chemokines are G protein–coupled receptors that show some promiscuity in terms of their binding of chemokines. The complexity of the chemokine–chemokine receptor family allows precise regulation of leukocyte trafficking, both within lymphoid organs and in the periphery.

24.6 Collaboration of Immune-System Cells in the Adaptive Response

An effective adaptive immune response requires the presence of B cells, T cells, and antigen-presenting cells. For B cells to execute class switch recombination and hypermutation—prerequisites for production of high-affinity antibodies—they require help from activated T cells. These T cells, in turn, can only be activated by professional antigen-presenting cells such as dendritic cells, which detect invaders using their Toll-like receptors (TLRs). The interplay between components of innate and adaptive immunity is therefore a very important aspect of adaptive immunity. In this section we describe how these various elements are activated and how the relevant cell types interact.

Toll-Like Receptors Perceive a Variety of Pathogen-Derived Macromolecular Patterns

An important part of innate defenses is the ability to immediately detect the presence of a microbial invader and respond to it. This response includes direct elimination of the invader, but it also prepares the mammalian host for a proper adaptive immune response, in particular through activation of professional antigen-presenting cells. Antigen-presenting cells are positioned throughout epithelia (airways, gastrointestinal tract, genital tract) where contact with pathogens is most likely to occur. In the skin a network of dendritic cells called *Langerhans cells* makes it virtually impossible for a pathogen that breaches this barrier to avoid contact with these professional antigen-presenting cells. Dendritic cells and other professional antigen-presenting cells detect the presence of bacteria and viruses through members of the Toll-like receptor (TLR) family. These proteins are named after the *Drosophila* protein Toll because of the structural and functional homology between them. *Drosophila* Toll was discovered because of its important role in dorsoventral patterning in the fruit fly, but related receptors are now recognized as capable of triggering an innate immune response in insects as well as in vertebrates.

TLR Structure Toll itself and all Toll-like receptors possess an extracellular domain composed of *leucine-rich repeats*. These repeats form a sickle-shaped extracellular domain believed to be involved in ligand recognition. The cytoplasmic portion of Toll-like receptors contains a domain responsible for the recruitment of adapter proteins to enable signal transduction. The signaling pathways engaged by the Toll-like receptors share many of the components

(and outcomes) as those used by receptors for the cytokine IL-1 (Figure 24-35).

The *Drosophila* Toll protein interacts with its ligand, Spaetzle, itself the product of a proteolytic conversion initiated by components of the cell wall of fungi that prey on *Drosophila*. In the fly, activation of Toll unleashes a signaling cascade that ultimately controls the transcription of genes that encode antimicrobial peptides. The activated receptor at the surface communicates with the transcriptional apparatus by means of a series of adapter proteins that activate downstream kinases interposed between the Toll-like receptor and the transcription factors that are activated by signaling from them. A key step is the ubiquitin-dependent proteasomal degradation of the Cactus protein. Its removal allows the protein Dif to enter the nucleus and initiate transcription. This pathway is highly homologous in its operation and structural composition to the NF- κ B pathway in mammals (see Figure 16-35).

Diversity of TLRs There are approximately a dozen mammalian Toll-like receptors that can be activated by various microbial products. These receptors are expressed by a variety of cell types, but their function is crucial for the activation of dendritic cells and macrophages. Neutrophils also express Toll-like receptors. The microbial products recognized by Toll-like receptors include macromolecules found in the cell envelope of bacteria such as lipopolysaccharides (LPS), flagellins (subunits of bacterial flagella), and bacterial lipopeptides. Although direct binding of these macromolecules to Toll-like receptors remains to be shown directly, their presence is sensed by distinct receptors: for example, TLR4 for lipopolysaccharide; heterodimeric of TLR1/2 TLR2/6 for lipopeptides; and TLR5 for flagellin. Recognition of all bacterial envelope components occurs at the cell surface.

A second set of Toll-like receptors—TLR3, TLR7, and TLR9—sense the presence of pathogen-derived nucleic acids. They do so not at the cell surface, but rather within the endosomal compartments where these receptors reside. Mammalian DNA is methylated at many CpG dinucleotides, whereas microbial DNA generally lacks this modification. TLR9 is activated by unmethylated, CpG-containing microbial DNA. Similarly, double-stranded RNA molecules present in some virus-infected cells lead to activation of TLR3. Finally, TLR7 responds to the presence of certain single-stranded RNAs. Thus the full set of mammalian TLRs allows the recognition of a variety of macromolecules that are diagnostic for the presence of bacterial, viral, and fungal pathogens.

TLR Signal Cascade As shown in Figure 24-35, engagement of mammalian Toll-like receptors leads to recruitment of the adapter protein MyD88, which in turn allows the binding and activation of IRAK (interleukin 1 receptor-associated kinase). After IRAK phosphorylates TNF-receptor associated factor 6 (TRAF6), several downstream kinases come into play, leading to release of active NF- κ B, a transcription factor, for translocation from the cytoplasm to the nucleus,

▲ **FIGURE 24-35 Toll-like receptors.** (a) Comparison of signal transduction from the IL-1 receptor and Toll-like receptor (TLR). Interleukin 1 (IL-1) binds to its receptor by co-engagement of the IL-1R accessory protein (IL-1R AcP). The adapter protein MyD88 is recruited to the activated receptor and in turn allows activation, by the interleukin-1 receptor associated kinase (IRAK), of the NF- κ B pathway (see Figure 16-35). Toll-like receptors, though structurally quite distinct from the IL-1R at their ligand-binding domains, also recruit MyD88 and IRAK to activate the NF- κ B pathway. (b) Structure of the human TLR3 extracellular domain structure. [Part (b) adapted from J. Choe et al., 2005, *Science* 309:581.]

where NF- κ B activates various target genes (see Figure 16-35). These target genes include those encoding IL-1 and IL-6, which contribute to inflammation, as well as the genes for tumor necrosis factor (TNF) and IL-12. Expression of type I interferons, small proteins with antiviral effects, is also turned on in response to TLR signaling.

Cell responses to TLR signaling are quite diverse. For antigen-presenting cells, these responses include not only production of cytokines but also the up-regulation of costimulatory molecules, the surface proteins important for full activation of naive T cells. TLR signaling allows dendritic cells to migrate from where they encounter a pathogen to the draining lymph nodes, where they may interact with naive lymphocytes. Not all activated Toll-like receptors evoke the identical response. Each activated TLR controls production of a particular set of cytokines by dendritic cells. For each engaged TLR, the combination of surface proteins and the cytokine profile induced by TLR engagement thus creates a unique phenotype for the activated dendritic cell. The identity of the microbe encountered sets the pattern of the TLRs that will be activated. These, in turn, shape the differentiation pathways of activated dendritic cells in terms of the cytokines produced, the surface molecules displayed, and the chemotactic cues to which the dendritic cells respond. The mode of activation of a dendritic cell and the cytokines it produces in response create a unique microenvironment in which T cells differentiate. Here they acquire the functional characteristics required to fight the infectious agent that led to engagement of the TLRs in the first place.

Engagement of Toll-Like Receptors Leads to Activation of Antigen-Presenting Cells

Professional antigen-presenting cells engage in continuous endocytosis, and in the absence of pathogens, they display at their surface class I and class II MHC molecules loaded with peptides derived from self-proteins. In the presence of pathogens, the Toll-like receptors on these cells are activated, inducing the antigen-presenting cells to become motile: They detach from the surrounding substratum and start to migrate in the direction of the draining lymph node, where the directional cues are provided by chemokines. An activated dendritic cell, for example, reduces its rate of antigen acquisition, up-regulates the activity of endosomal/lysosomal proteases, and increases the transfer of class II MHC-peptide complexes from the loading compartments to the cell surface. Finally, activated professional antigen-presenting cells up-regulate expression of the costimulatory molecules CD80 and CD86, which will allow them to activate T cells more effectively. The initial contact of a professional antigen-presenting cell with a pathogen thus results in its migration to the draining lymph node in a state that is fully capable of activating a naive T cell. Antigen is displayed in the form of peptide-MHC complexes, costimulatory molecules are abundantly present, and cytokines are produced that assist in setting up the proper differentiation program for the T cells to be activated.

Antigen-laden dendritic cells engage antigen-specific T cells, which respond by proliferating and differentiating. The cytokines produced in the course of this priming reaction determine whether a CD4 T cell will polarize towards an inflammatory or a helper cell phenotype. If engagement occurs via class I MHC molecules, a CD8 T cell may develop from a precursor cytotoxic T cell to a fully active cytotoxic T cell. The activated T cells are motile and move through the lymph node, in preparation for their encounter with B cells, or in order to contact the vasculature, enter the circulation, and leave the lymph node to execute effector functions elsewhere in the body.

Production of High-Affinity Antibodies Requires Collaboration Between B and T Cells

In order to generate high-affinity antibodies, which are better at binding antigen and at neutralizing pathogens, B cells require assistance from T cells. Thus, B-cell activation requires a source of antigen to engage the B-cell receptor and the presence of activated antigen-specific T cells. Soluble antigen reaches the lymph node through the afferent lymphatics (see Figure 24-6). Bacterial growth is accompanied by the release of microbial products that can serve as antigens. If the infection is accompanied by local tissue destruction, activation of the complement cascade results in bacterial killing and concomitant release of bacterial proteins, which are also delivered via the lymphatics to the draining lymph node. Complement-modified antigens are superior in the activation of B cells through engagement of complement receptors on B cells, which serve as co-receptors for the B-cell receptor. B cells that acquire antigen via their B-cell receptors internalize the immune complex and process it for presentation via the class II MHC pathway. Antigen-experienced B cells thus convert the BCR-acquired antigen into a call for T-cell help in the form of a class II MHC-peptide complex (Figure 24-36). Note that the epitope recognized by the B-cell receptor may be quite distinct from the peptide ultimately displayed on the surface associated with a class II MHC molecule. As long as the B-cell epitope and the class II-presented peptide—a T-cell epitope—are physically linked, successful B-cell differentiation can be initiated.

The concept of linked recognition explains why there is a minimum size to, for example, peptides to be used successfully as antigens in elicitation of a high-affinity antibody response. Such peptides must fulfill several criteria: They must contain the epitope seen by the B-cell receptor, survive endocytosis and proteolysis, and bind to the allelic class II MHC molecules available in order to be presented as a class II MHC-peptide complex, which serves as a call for T-cell help. For this reason, synthetic peptides used to elicit antibodies are conjugated to carrier proteins to improve their immunogenicity. Only through recognition of this class II MHC-peptide complex via its T-cell receptor can T cells provide the help necessary for the B cell to run its complete course of differentiation.

This concept applies equally to B cells capable of recognizing particular modifications on proteins or peptides. Antibodies that recognize the phosphorylated form of a kinase are commonly raised by immunization of experimental animals

▲ **FIGURE 24-36 Collaboration between T and B cells required to initiate the production of antibodies.** (Left) Activation of T cells by means of antigen-loaded dendritic cells (DCs). (Right) Antigen acquisition by and subsequent activation of B cells. Step **1**: Professional antigen-presenting cells (DCs, B cells) acquire antigen. Step **2**: Antigen is internalized, processed, and presented to T cells. T-cell activation occurs when dendritic cells present antigen to T cells. Step **3a**: Activated T cells engage antigen-experienced B cells through peptide-MHC complexes displayed on the surface of the B cell. Step **3b**: T cells that are persistently activated initiate expression of the CD40

ligand (CD40L), a prerequisite for B cells becoming fully activated and turning on the enzymatic machinery (activation-induced deaminase) to initiate class switch recombination and somatic hypermutation. Step **4a**: A B cell that receives the appropriate instructions from CD4 helper T cells becomes an IgM-secreting plasma cell. Step **4b**: A B cell that receives signals from activated CD4 helper T cells in the form of CD40-CD40L interactions and the appropriate cytokines can class switch to other immunoglobulin isotypes and engage in somatic hypermutation.

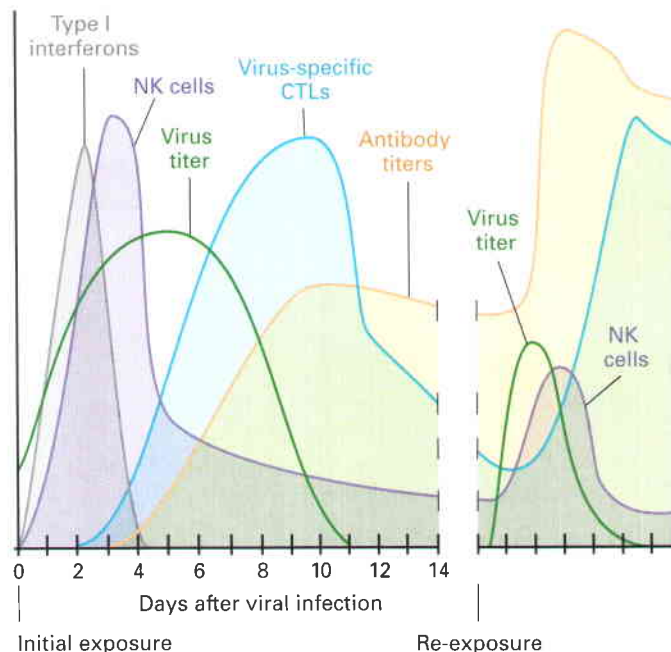

with the phosphorylated peptide in question, conjugated to a carrier protein. An appropriately specific B cell recognizes the phosphorylated site on the peptide of interest, internalizes the complex between phosphorylated peptide and carrier, and generates a complex set of peptides by endosomal proteolysis of the carrier protein. Among these peptides there should be at least one that can bind to the class II MHC molecules carried by that B cell. If properly displayed at the surface of the B cell, this class II MHC–peptide complex becomes the call for T-cell help, provided by CD4 T cells equipped with receptors capable of recognizing the complex of class II MHC molecule and carrier-derived peptide.

The T cell identifies, via its T-cell receptor, an antigen-experienced B cell by means of the class II MHC–peptide complexes displayed by the B cell. The B cell also displays costimulatory molecules and receptors for cytokines produced by the activated T cell (e.g., IL-4). These B cells then proliferate. Some of them differentiate into plasma cells; others are set aside and become memory B cells. The first wave of antibodies produced is always IgM. Class switching to other isotypes and somatic hypermutation (necessary for the generation and selection of high-affinity antibodies) requires the persistence of antigen or repeated exposure to antigen. In addition to cytokines, B cells require cell-cell contacts to initiate somatic hypermutation and class switch recombination. These contacts involve CD40 protein on B cells and CD40L on T cells. These proteins are members of the TNF–TNF receptor family.

Vaccines Elicit Protective Immunity Against a Variety of Pathogens

 Arguably the most important application of immunological principles are vaccines. Vaccines are materials designed to be innocuous but that can elicit an immune response for the purpose of providing protection against a challenge with the virulent version of that pathogen (Figure 24-37). It is not always known why such vaccines are as successful as they are, but in many cases, the ability to raise antibodies that can neutralize the pathogen (viruses) or that show microbicidal effects (bacteria) are good indicators of successful vaccination.

Several strategies can lead to a successful vaccine. Vaccines may be composed of live attenuated variants of more virulent pathogens. Serial passage in tissue culture or from animal to animal will often lead to *attenuation*, the molecular basis for which is not well understood. The attenuated version of the pathogen causes a mild form of the disease or causes no symptoms at all. However, by recruiting all the component parts of the adaptive immune system, such live attenuated vaccines can elicit protective levels of antibodies. These antibody levels may wane with advancing age, and repeated immunizations (booster injections) are often required to maintain full protection. Live attenuated vaccines are in use against flu, measles, mumps, and tuberculosis. In the latter case, an attenuated strain of the mycobacterium that causes the disease is used (Bacille Calmette-Guerin; BCG). Although live attenuated poliovirus was used as a vaccine until recently, its use was discontinued because the risk of

▲ FIGURE 24-37 Time course of a viral infection. The initial antiviral response, seen when the numbers of infectious particles rises, includes activation of natural killer (NK) cells and production of type I interferons. These responses are part of innate defenses. The production of antibodies, as well as the activation of cytotoxic T cells (CTLs) follows, and eventually clears the infection. Re-exposure to the same virus leads to more rapid and more pronounced production of antibodies and to more rapid activation of cytotoxic T cells. A successful vaccine induces an immune response similar in some respects to that following initial exposure to a pathogen, but without causing significant symptoms of disease. If a vaccinated person subsequently is exposed to that pathogen, the adaptive immune system is primed to respond quickly and strongly.

re-emergence of more virulent strains of the poliovirus outweighed the benefit. Currently, killed poliovirus is used as the vaccine of choice.

Vaccines based on the cowpox virus, a close relative of the human pathogen variola responsible for smallpox, have been used successfully to completely eradicate smallpox, the first such example of the elimination of an infectious disease. Attempts to achieve a similar feat for polio are nearing completion.

The other major type of vaccine is called a subunit vaccine. Rather than using live attenuated strains of a virulent bacterium or virus, only one of its components is used to elicit immunity. In certain cases this is sufficient to afford lasting protection against a challenge with the live, virulent source of the antigen used for vaccination. This approach has been successful in preventing infections with the hepatitis B virus. The commonly used flu vaccines are composed mostly of the envelope proteins neuraminidase and hemagglutinin (see Figure 3-10); these vaccines elicit neutralizing antibodies. For the human papillomavirus HPV 16, a serotype that causes cervical cancer, virus-like particles are generated composed of the virus capsid proteins, but devoid of its genetic material; these virus-like particles are noninfectious, yet

in many respects mimic the intact virion. The HPV vaccine now licensed for use in humans is expected to reduce the incidence of cervical cancer in susceptible populations by perhaps as much as 80 percent, the first example of a vaccine that prevents this particular type of cancer.

From a public health perspective, cheaply produced and widely distributed vaccines are formidable tools in eradicating communicable diseases. Current efforts are aimed at producing vaccines against diseases for which no other suitable therapies are available (Ebola virus) or where socioeconomic conditions have made distribution of drugs problematic (malaria, HIV/AIDS). Through a more complete understanding of how the immune system operates, it should be possible to improve on the design of existing vaccines and extend these principles to diseases for which currently no successful vaccines are available. ■

KEY CONCEPTS OF SECTION 24.6

Collaboration of Immune-System Cells in the Adaptive Immune Response

- Antigen-presenting cells such as dendritic cells require activation by means of signals delivered to their Toll-like receptors. These receptors are broadly specific for macromolecules produced by bacteria and viruses. Engagement of Toll-like receptors activates the NF- κ B signaling pathway, whose outputs include the synthesis of inflammatory cytokines (see Figure 24-35).
- Upon activation, dendritic cells become migratory and move to lymph nodes, ready for their encounter with T cells. Activation of dendritic cells also increases their display of MHC-peptide complexes and expression of costimulatory molecules required for initiation of a T-cell response.
- B cells require assistance of activated T cells to execute their full differentiation program to become plasma cells. Antigen-specific help is provided to B cells by activated T cells, which recognize class II MHC-peptide complexes on the surface of B cells. These B cells generate the relevant MHC-peptide complexes by internalizing antigen via BCR-mediated endocytosis, followed by antigen processing and presentation via the class II MHC pathway (see Figure 24-36).
- In addition to cytokines produced by activated T cells, B cells require cell-cell contact to initiate somatic hypermutation and class switch recombination. This involves CD40 on B cells and CD40L on T cells.
- Important applications of the immunological concept of collaboration between T and B cells include vaccines. The most common forms of vaccines are live attenuated viruses or bacteria, which can evoke a protective immune response without causing pathology, and subunit based vaccines.

Perspectives for the Future

Several areas of immunological research promise to have a major impact. The generation of new vaccines that are both

safe and effective remains a goal of enormous practical and societal significance: HIV infection, drug-resistant tuberculosis, and malaria are three examples of major killers, each responsible for millions of deaths annually, for which no successful vaccines are currently available. Research must incorporate cell biological as well as immunological concepts to solve this unmet need. Even though some of the most successful vaccines were developed in the absence of detailed immunological knowledge, the current regulatory climate demands a more detailed understanding of the composition of a successful vaccine and why such vaccines work.

Lymphocytes are among the few cell types that can be studied as primary cells that continue to perform cell- and tissue-type specific behavior in tissue culture. This trait makes lymphocytes an attractive model in which to study details of signal transduction, to explore interactions between well-defined, different cell types under defined laboratory conditions, and to accurately measure and model the responses evoked by specific stimuli.

The ability of lymphocytes to create antigen-specific receptors of nearly limitless variability comes at a price: the generation of self-reactive receptors, which is the major contributing factor to autoimmune disease. Vertebrates have several mechanisms for keeping such self-reactive lymphocytes in check, but none of them is fool-proof. We must understand how tolerance to self-antigens is generated, maintained, and ultimately broken at the onset of autoimmune disease. This understanding should help define new strategies for manipulating and controlling self-reactive lymphocytes to prevent or treat autoimmune diseases (e.g., type I diabetes, multiple sclerosis, and arthritis).

With advances in understanding of stem cells and how to use stem cells for therapy in the treatment of diseases (e.g., Parkinson's disease, muscular dystrophy, and spinal cord injuries), transplantation of heterologous stem cells (i.e., derived from an individual other than the patient) is one of several options. The immune system's ability to recognize as foreign such transplanted stem-cell derivatives is a factor that will limit the use of heterologous stem cells. Consequently, new means to suppress responses to these transplants, or to induce tolerance to them, are important goals.

More refined genetic tools continue to allow identification of additional lymphocyte subsets, often with distinct functions. Improved classification schemes will help in understanding lymphocyte function, and so open the door to selective manipulation of lymphocyte function for therapeutic gain.

Our understanding of the interplay between innate and adaptive immune responses, and the many ways in which pathogens interfere in both innate and adaptive immunity, will benefit from our increased understanding of genome sequences and genome structures, both host and pathogen. The use of genetically modified pathogenic organisms as probes for host immune function will help our understanding of basic immunology. This is a rapidly expanding area of basic cell biological research.

Review the Concepts

1. Describe the ways in which each of the following pathogens can disarm or manipulate their host's immune system to their own advantage: (a) pathogenic strains of *Staphylococcus aureus* and (b) enveloped viruses.
2. Trace the course of leukocytes as they perform their functions throughout the body.
3. Identify the major mechanical and chemical defenses that protect internal tissues from microbial attack.
4. Compare the classical pathway of complement activation to the alternative pathway.
5. What evidence led Emil von Behring to discover antibodies and the complement system in 1905?
6. What is opsonization? What is the role of antibodies in this process?
7. In B cells, what mechanism insures that only rearranged V genes are transcribed?
8. What prevents further rearrangement of immunoglobulin heavy-chain gene segments in a pre-B cell once a productive heavy-chain rearrangement has occurred?
9. How do antibodies undergo a class switch from producing IgM antibodies to any of the other isotypes?
10. What biochemical mechanism underlies affinity maturation of the antibody response?
11. Compare the structures of class I and class II MHC molecules. What kinds of cells express each class of MHC molecule? What are their functions?
12. Describe the six steps in antigen processing and presentation via the class I MHC restricted pathway.

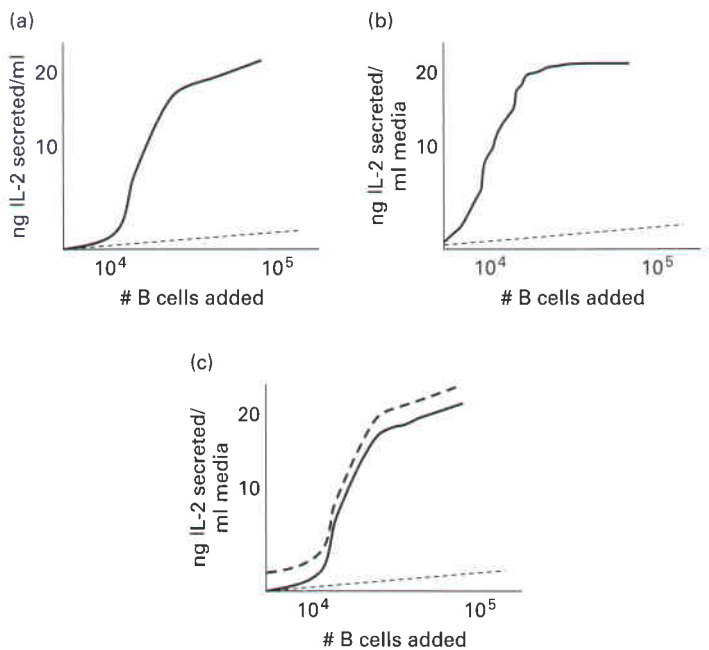

13. Describe the six steps in antigen processing and presentation via the class II MHC restricted pathway.
14. What prevents self-reactive T cells from leaving the thymus?
15. Explain why T-cell mediated autoimmune diseases are associated with particular alleles of class II MHC genes.
16. How are antigen-presenting cells and helper T cells involved in B-cell activation?

Analyze the Data

To understand how ovalbumin (a protein from chicken eggs) and other foreign antigens in the cytoplasm of a cell are presented for immunosurveillance, ovalbumin can be introduced by electroporation into the cytoplasm of mouse primary B lymphocytes. The ovalbumin is cleaved, and one of its cleavage products is a peptide with the sequence SIINF EKL (single-letter abbreviations). When these B cells are mixed with a clonal T-cell population that specifically recognizes SIINF EKL in the context of MHC molecules, the T cells become stimulated. The graphs below show the secretion of IL-2 after these T cells were mixed with B cells that had been treated in various ways.

Graph A: B cells were electroporated either with ovalbumin (solid line) or with a control protein (dashed line) not recognized by this clonal T-cell population.

Graph B: B cells were first incubated with an inhibitor of lysosomal cysteine proteases (solid line) or an inhibitor of the proteasome (dashed line) and then electroporated with ovalbumin.

Graph C: B cells were exposed to a high concentration of the SIINF EKL peptide and then immediately fixed [killed] (dotted curve) with formaldehyde or incubated for two hours in the presence (dashed curve) or absence (solid curve) of the proteasome inhibitor and then fixed with formaldehyde.

a. Under what conditions is IL-2 secreted? Is it likely that the T cells or the B cells are secreting IL-2?

b. What information is derived from the use of the lysosomal and the proteasome inhibitors? Is the ovalbumin peptide more likely to be presented complexed with class I MHC or class II MHC molecules? What is the most likely pathway by which ovalbumin in the cytoplasm of the B cell is presented for recognition by the appropriate T cells?

c. Why do you think that the presence or absence of the proteasome inhibitor in experiment C had no effect on the amount of IL-2 secreted, whereas the presence of the inhibitor in experiment B shows a marked effect?

TWO GENES BECOME ONE: SOMATIC REARRANGEMENT OF IMMUNOGLOBULIN GENES

N. Hozumi and S. Tonegawa, 1976, *Proc. Nat'l. Acad. Sci. USA* 73:3629

For decades, immunologists wondered how the body could generate the multitude of pathogen-fighting immunoglobulins, called antibodies, needed to ward off the vast array of different bacteria and viruses encountered in a lifetime. Clearly, these protective proteins, like all proteins, somehow were encoded in the genome. But the enormous number of different antibodies potentially produced by the immune system made it unlikely that individual immunoglobulin (Ig) genes encoded all the possible antibodies an individual might need. In studies beginning in the early 1970s, Susumu Tonegawa, a molecular biologist, laid the foundation for solving the mystery of how antibody diversity is generated.

Background

Research on the structure of Ig molecules provided some clues about the generation of antibody diversity. First, it was shown that an Ig molecule is composed of four polypeptide chains: two identical heavy (H) chains and two identical light (L) chains. Some researchers proposed that antibody diversity resulted from different combinations of heavy and light chains. Although somewhat reducing the number of genes needed, this hypothesis still required that a large portion of the genome be devoted to Ig genes. Protein chemists then sequenced several Ig light and heavy chains. They found that the C-terminal regions of different light chains were very similar and thus were termed the constant (C) region, whereas the N-terminal regions were highly variable and thus were termed the variable (V) region. The sequences of different heavy chains exhibited a similar pattern. These findings suggested that the genome contains

a small number of C genes and a much larger group of V genes.

In 1965, W. Dryer and J. Bennett proposed that two separate genes, one V gene and one C gene, encode each heavy chain and each light chain. Although this proposal seemed logical, it violated the well-documented principle that each gene encodes a single polypeptide. To avoid this objection, Dryer and Bennett suggested that a V and C gene somehow were rearranged in the genome to form a single gene, which then was transcribed and translated into a single polypeptide, either a heavy or light chain. Indirect support for this model came from DNA hybridization studies showing that only a small number of genes encoded Ig constant regions. However, until more powerful techniques for analyzing genes came on the scene, a definitive test of the novel two-gene model was not possible.

The Experiment

Tonegawa realized that if immunoglobulin genes underwent rearrangement, then the V and C genes were most likely located at different points in the genome. The discovery of restriction endonucleases, enzymes that cleave DNA at specific sites, had allowed some bacterial genes to be mapped. However, because mammalian genomes are much more complex, similar mapping of the genes encoding V and C regions was not technically feasible. Instead, drawing on newly developed molecular biology techniques, Tonegawa devised another approach for determining whether the V and C regions were encoded by two separate genes. He reasoned that if rearrangement of the V and C genes occurs, it must happen during differentiation of Ig-secreting B cells from embryonic cells. Furthermore, if

rearrangement occurs, there should be detectable differences between unrearranged germ-line DNA from embryonic cells and the DNA from Ig-secreting B cells. Thus, he set out to see if such differences existed using a combination of restriction-enzyme digestion and RNA-DNA hybridization to detect the DNA fragments.

He began by isolating genomic DNA from mouse embryos and from mouse B cells. To simplify the analysis, he used a line of B-cell tumor cells, all of which produce the same type of antibody. The genomic DNA was then digested with the restriction enzyme *Bam*HI, which recognizes a sequence that occurs relatively rarely in mammalian genomes. Thus, the DNA was broken into many large fragments. He then separated these DNA fragments by agarose gel electrophoresis, which separates biomolecules on the basis of charge and size. Since all DNA carries an overall negative charge, the fragments were separated based on their size. Next, he cut the gel into small slices and isolated the DNA from each slice. Now, Tonegawa had many fractions of DNA pieces of various sizes. He then could analyze these DNA fractions to determine if the V and C genes resided on the same fragment in both B cells and embryonic cells.

To perform this analysis, Tonegawa first isolated from the B-cell tumor cells the mRNA encoding the major type of Ig light chain, called κ . Since a RNA is complementary to one strand of the DNA from which it is transcribed, it can hybridize with this strand forming a RNA-DNA hybrid. By radioactively labeling the entire κ mRNA, Tonegawa produced a probe for detecting which of the separated DNA fragments contained the κ chain gene. He then isolated the 3' end of the

▲ FIGURE 1 Experimental results showing that the genes encoding the variable (V) and constant (C) regions of κ light chains are rearranged during development of B cells. These curves depict the hybridization of labeled RNA probes, specific for the

entire κ gene (V + C) and for the 3' end that encodes the C region, to fractions of digested embryonic or B-cell DNA separated by agarose gel electrophoresis. [Adapted from N. Hozumi and S. Tonegawa, 1976, *Proc. Nat'l. Acad. Sci. USA* 73:3629.]

κ mRNA and labeled it, yielding a second probe that would detect only the DNA sequences encoding the constant region of the κ chain. With these probes in hand—one specific for the combined V + C gene and one specific for C alone—Tonegawa was ready to compare the DNA fragments obtained from B cells and embryonic cells.

He first denatured the DNA in each of the fractions into single strands and then added one or the other labeled probe. He found that the C-specific probe hybridized to different fractions derived from embryonic and B-cell DNA (Figure 1). Even more telling, the full-length RNA probe hybridized to two *different* fractions of the embry-

onic DNA, suggesting that the V and C genes are not connected and that a cleavage site for *Bam*HI lies between them. Tonegawa concluded that during the formation of B cells, separate genes encoding the V and C regions are rearranged into a single DNA sequence encoding the entire κ light chain (Figure 2).

Discussion

The generation of antibody diversity was a problem awaiting development of powerful molecular techniques to answer it. Tonegawa went on to clone V-region genes and prove that the rearrangement must occur somatically.

These findings impacted genetics as well as immunology. Where once it was believed that every cell in the body contained the same genetic information, it became clear that some cells take that information and alter it to suit other purposes. In addition to somatic rearrangement, Ig genes undergo a variety of other alterations that allow the immune system to create the diverse repertoire of antibodies necessary to react to any invading organism. Our current understanding of these mechanisms rests on the foundation of Tonegawa's fundamental discovery. For this work, he received the Nobel Prize for Physiology and Medicine in 1987.

◀ FIGURE 2 Schematic diagram of κ light-chain DNA in embryonic cells and B cells that is consistent with Tonegawa's results. In embryonic cells, cleavage with the *Bam*HI restriction enzymes (red arrows) produces two different sized fragments, one containing the V gene and one containing the C gene. In B cells, the DNA is rearranged so that the V and C genes are adjacent, with no intervening cleavage site. *Bam*HI digestion thus yields one fragment that contains both the V and C genes.

CANCER

Melanoma tumor in human skin, stained with hematoxylin and eosin. Underlying the relatively normal epithelium at the top are invasive melanoma cells, many with small dark nuclei and some producing brown melanotic inclusions. Melanoma tumors are malignant, moving from their original sites in the skin to seed new tumors in a variety of tissues; these metastases can be fatal. Worldwide each year, about 48,000 people die from melanoma and 160,000 new cases are detected. The only treatment is early detection and excision. (Courtesy of Anthony Oro, Sam Dadras, and Matthew Scott.)

Cancer causes about one-fifth of the deaths in the United States each year. Worldwide, between 100 and 350 of each 100,000 people die of cancer each year. Cancer is due to failures of the mechanisms that usually control the growth and proliferation of cells. During normal development and throughout adult life, intricate genetic control systems regulate the balance between cell birth and death in response to growth signals, growth-inhibiting signals, and death signals. Cell birth and death rates determine adult body size, and the rate of growth in reaching that size. In some adult tissues, cell proliferation occurs continuously as a constant tissue-renewal strategy. Intestinal epithelial cells, for instance, live for just a few days before they die and are replaced; certain white blood cells are replaced as rapidly, and skin cells commonly survive for only 2–4 weeks before being shed. The cells in many adult tissues, however, normally do not proliferate except during healing processes. Such stable cells (e.g., hepatocytes, heart muscle cells, neurons) can remain functional for long periods or even for the entire lifetime of an organism. Cancer occurs when the mechanisms that maintain these normal growth rates malfunction to cause excess cell division.

The losses of cellular regulation that give rise to most or all cases of cancer are due to genetic damage that is often accompanied by influences of tumor-promoting chemicals, hormones, and sometimes viruses (Figure 25-1). Mutations in two broad classes of genes have been implicated in the onset of cancer: **proto-oncogenes** and **tumor-suppressor genes**. Proto-oncogenes normally promote cell growth; they are changed into **oncogenes** by mutations that cause the gene to be excessively active in growth promotion. Either increased

gene expression or production of a hyperactive product will do it. Tumor-suppressor genes normally restrain growth, so mutations that inactivate them allow inappropriate cell division. A third, more specialized, class of genes called **caretaker genes** are also often linked to cancer. Caretaker genes normally protect the integrity of the genome; when they are inactivated, cells acquire additional mutations at an increased rate—including mutations that damage growth control and lead to cancer. Many of the genes in these three classes encode proteins that help regulate cell birth (i.e., entry into and progression through the cell cycle) or cell death by **apoptosis**; others encode proteins that participate in repairing damaged DNA.

Cancer commonly results from mutations that arise during a lifetime's exposure to **carcinogens**, substances encountered in the environment, which include certain chemicals and

▲ **FIGURE 25-1 Overview of changes in cells that cause cancer.** During carcinogenesis, six fundamental cellular properties are altered, as shown here in this tumor growing within normal tissue, to give rise to the complete, most destructive cancer phenotype. Less dangerous tumors arise when only some of these changes occur. In this chapter we examine the genetic changes that result in these altered cellular properties. [Adapted from D. Hanahan and R. A. Weinberg, 2000, *Cell* 100:57.]

ultraviolet radiation. Most cancer cells lack one or more DNA repair systems, which may explain the large number of mutations they accumulate. Although DNA-repair enzymes do not directly inhibit cell proliferation, cells that have lost the ability to repair errors, gaps, or broken ends in DNA accumulate mutations in many genes, including those that are critical in controlling cell growth and proliferation. Thus loss-of-function mutations in caretaker genes such as the genes encoding DNA-repair enzymes prevent cells from correcting mutations that inactivate tumor-suppressor genes or activate oncogenes.

Cancer-causing mutations occur mostly in somatic cells, not in the germ-line cells, and somatic cell mutations are not passed on to the next generation. In contrast, certain inherited mutations, which are carried in the germ line, increase the probability that cancer will occur at some time. In a destructive partnership, somatic mutations can combine with inherited mutations to cause cancer.

Thus the cancer-forming process, called *oncogenesis* or *tumorigenesis*, is an interplay between genetics and the environment. Most cancers arise after genes are altered by carcinogens or by errors in the copying and repair of genes. Even if the genetic damage occurs only in one somatic cell, division of this cell will transmit the damage to the daughter cells, giving rise to a **clone** of altered cells. Rarely, however, does mutation in a single gene lead to the onset of cancer. More typically, a series of mutations in multiple genes creates a progressively more rapidly proliferating cell type that escapes normal growth restraints, creating an opportunity for additional mutations. The cells also acquire other properties that give them an advantage, such as the ability to escape from normal epithelia and stimu-

late the growth of vasculature to obtain oxygen. Eventually the clone of cells grows into a **tumor**. In some cases cells from the primary tumor migrate to new sites where they form secondary tumors, a process termed **metastasis**. Most cancer deaths are due to invasive, fast-growing metastasized tumors.

Metastasis is a complex process with many steps. Invasion of new tissues is nonrandom, depending on the nature of both the metastasizing cell and the invaded tissue. Metastasis is facilitated if the tumor cells produce growth factors and angiogenesis factors (inducers of blood vessel growth). Motile, invasive cells are most dangerous. Tissues under attack, such as bone, blood vessels, and liver, are most vulnerable if they produce growth factors and readily grow new vasculature, since these help to support the invaders. They are more resistant if they produce (1) anti-proliferative factors that restrain tumor cell division, (2) inhibitors of proteolytic enzymes; these block cancer cell proteases that are used to penetrate tissue, and (3) anti-angiogenesis factors that stop tumor cells from spurring the growth of blood vessels.

Research on the genetic foundations of a particular type of cancer often begins by identifying one or more genes that are mutationally altered in tumor cells. Subsequently it is important to learn whether an altered gene is a contributing cause for the tumor, or an irrelevant side event. Such investigations usually employ multiple approaches: epidemiological comparisons of the frequency with which the genetic change is associated with a type of tumor, tests of the growth properties of cells in culture that have the particular mutation, and the construction of mouse models of the disease to see the effects of mutating a putative cancer-related gene. A more sophisticated analysis is possible when the altered gene is known to encode a component of a particular molecular pathway (e.g., an intracellular signaling pathway). In this case it is possible to alter other components of the same pathway and see whether the same type of cancer arises.

Time plays an important role in cancer. Many years may be required to accumulate the multiple mutations that are required to form a tumor, so most cancers develop later in life. The requirement for multiple mutations also lowers the frequency of cancer compared with what it would be if tumorigenesis were triggered by a single mutation. However, huge numbers of cells are, in essence, mutagenized and tested for altered growth during our lifetimes, a powerful selection in favor of cells which, in this case, we do not want. Cells that proliferate quickly become more abundant, undergo further genetic changes, and can become progressively more dangerous. Furthermore, cancer occurs most frequently after the age of reproduction, and therefore plays a lesser role in reproductive success. So cancer is common, in part reflecting increasingly long human lives but also perhaps reflecting the lack of evolutionary selection against the disease.

In this chapter, we first introduce the properties of tumor cells and describe the multistep process of oncogenesis. Next, we consider the general types of genetic changes that lead to the unique characteristics of cancer cells, and the interplay between somatic and inherited mutations. The following sections examine in detail how mutations affecting both growth-promoting and growth-inhibiting processes can

result in excess cell proliferation. We conclude the chapter with a discussion of the role of carcinogens and how a breakdown in DNA repair mechanisms, by the loss of caretaker genes or the activation of a telomerase enzyme that allows more cell divisions, can lead to oncogenesis.

25.1 Tumor Cells and the Onset of Cancer

Before examining in detail the genetic basis of cancer, we consider the properties of tumor cells that distinguish them from normal cells and the general process of tumorigenesis. The change from a normal cell into a cancer cell commonly involves multiple steps, each one adding properties that make cells more likely to grow into a tumor. The genetic changes that underlie oncogenesis alter several fundamental properties of cells, allowing cells to evade normal growth controls and ultimately conferring the full cancer phenotype (see Figure 25-1). Cancer cells acquire a drive to proliferate that does not require an external inducing signal. They fail to sense signals that restrict cell division and continue to live when they should die. They often change their attachment to surrounding cells or the extracellular matrix, breaking loose to move away and spread the tumor. A cancer cell may, up to a point, resemble a particular type of normal, rapidly dividing cell, but the cancer cell and its progeny will be immortal. Tumors are characteristically *hypoxic* (oxygen-starved), so to grow to more than a small size, tumors must obtain a blood supply. They often do so by signaling to induce the growth of blood vessels into the tumor. As cancer progresses, tumors become an abnormal organ, increasingly well adapted to growth and invasion of surrounding tissues.

Normal animal cells are often classified according to their embryonic tissue of origin, and the naming of tumors has followed suit. Malignant tumors are classified as *carcinomas* if they derive from epithelia such as endoderm (gut epithelium) or ectoderm (skin and neural epithelia), and *sarcomas* if they

derive from mesoderm (muscle, blood, and connective tissue precursors). Carcinomas are by far the most common type of malignant tumor (more than 90 percent). The *leukemias*, a class of sarcomas, grow as individual cells in the blood, whereas most other tumors are solid masses. (The name *leukemia* is derived from the Greek for “white blood”: the massive proliferation of leukemic cells can cause a patient’s blood to appear milky.) The *lymphomas*, another type of malignant sarcoma, are solid tumors of lymphocytes and plasma cells. Malignant brain tumors can be derived from neural cells, and *glioblastomas* are tumors of the glial cells that constitute the major cell type in the brain.

Metastatic Tumor Cells Are Invasive and Can Spread

Tumors arise with great frequency, especially in older individuals, but most pose little risk to their host because they are localized, and of small size. We call such tumors **benign**; an example is warts, a benign skin tumor. The cells composing benign tumors closely resemble, and may function like, normal cells. The cell-adhesion molecules that hold tissues together keep benign tumor cells, like normal cells, localized to the tissues where they originate. A fibrous capsule usually delineates the extent of a benign tumor and makes it an easy target for a surgeon. Benign tumors become serious medical problems only if their sheer bulk interferes with normal functions or if they secrete excess amounts of biologically active substances like hormones. Acromegaly, the overgrowth of head, hands, and feet, for example, can occur when a benign pituitary tumor causes overproduction of growth hormone.

In contrast, cells composing a **malignant tumor**, or **cancer** (Figure 25-2), usually grow and divide more rapidly than normal, and fail to die at the normal rate (e.g., chronic lymphocytic leukemia, a tumor of white blood cells). A key characteristic of malignant cells is their ability to invade nearby tissue, spreading and seeding additional tumors while the cells

▲ **FIGURE 25-2** Gross and microscopic views of a tumor invading normal liver tissue. (a) The gross morphology of a human liver in which a metastatic lung tumor is growing. The white protrusions on the surface of the liver are the tumor masses. (b) A

light micrograph of a section of the tumor in (a) showing areas of small, dark-staining tumor cells invading a region of larger, light-staining, normal liver cells. [Courtesy of J. Braun.]

continue to proliferate. Some malignant tumors, such as those in the ovary or breast, remain localized and encapsulated, at least for a time. When these tumors progress, the cells invade surrounding tissues, and undergo metastasis (Figure 25-3a). Most malignant cells eventually acquire the ability to metastasize. Thus the major characteristics that differentiate metastatic (or malignant) tumors from benign ones are their abilities to invade nearby tissues and spread to distant ones.

Normal cells are restricted to their place in an organ or tissue by cell-cell adhesion and by physical barriers such as the *basement membrane*, which underlies layers of epithelial

(c) Components of invadopodia

Actin regulation: Cortactin, N-WASP, Arp2/3 complex, WIP, cofilin, tatin
 Signaling/adaptors: Cdc42, Nck1, p190RhoGAP, Src, FAK, PKC μ , AMAP1
 Adhesion: Integrins, vinculin, paxillin, tensin
 Proteases: MMP2, MT1-MMP, seprase, invadolysin
 Membrane remodeling: Dynamin-2, Art6, synaptojanin-2

▲ **FIGURE 25-3 Metastasis.** (a) First steps in metastasis, using breast carcinoma cells as an example. Cancer cells leave the main tumor and attack the basement membrane, using extracellular matrix (ECM) fibers to reach the blood vessels. The cancer cells can be attracted by signals such as epidermal growth factor (EGF), which can be secreted by macrophages (yellow). At the blood vessels they penetrate the layer of endothelial cells that forms the vessel walls, and enter the bloodstream. (b) Carcinoma cells penetrate the extracellular matrix and blood vessel wall by extending “invadopodia,” which produce matrix metalloproteases and other proteases to open up a path. (c) Proteins used by invadopodia. N-WASP (Chapter 17) controls the assembly of actin into filaments that form the internal skeleton of the invadopodia. One hope for fighting cancer is to develop drugs that target components of the invasion and metastasis process without blocking normal essential functions. [Adapted from Yamaguchi et al., 2005, *Curr. Opin. Cell Biol.* **17**:559.]

cells and also surrounds the endothelial cells of blood vessels (Chapter 19). Cancer cells have a complex relation to the extracellular matrix and basement membrane. They can penetrate the matrix using a cell protrusion called an “invadopodium,” formed by the localized assembly of an actin cytoskeleton (Figure 25-3b). The cells must degrade the basement membrane to penetrate it and metastasize, but in some cases cells may migrate along the membrane. Many tumor cells secrete a protein (plasminogen activator) that converts the serum protein plasminogen to the active protease plasmin. Increased plasmin activity, together with other protease activities, promotes metastasis by digesting the basement membrane, thus allowing its penetration by tumor cells (Figure 25-3b). As the basement membrane disintegrates, some tumor cells will enter the blood, but fewer than 1 in 10,000 cells that escape the primary tumor survive to colonize another tissue and form a secondary, metastatic tumor. In addition to escaping the original tumor and entering the blood, cells that will seed new tumors must then adhere to an endothelial cell lining a capillary and migrate across or through it into the underlying tissue. The multiple crossings of tissue layers that underlie malignancy often involve new or variant surface proteins made by malignant cells (Figure 25-3c).

In addition to important changes in cell-surface proteins, drastic changes occur in the cytoskeleton during tumor-cell formation and metastasis. These alterations can result from changes in the expression of genes encoding Rho and other small GTPases that regulate the actin cytoskeleton (Chapter 17). For instance, tumor cells have been found to overexpress the *RhoC* gene, which encodes a protein that promotes actin/myosin contraction in cells, and this increased RhoC activity stimulates metastasis.

Cancer cells can often be distinguished from normal cells by microscopic examination. They are usually less well differentiated than normal cells or benign tumor cells. In a specific tissue, malignant cells usually exhibit the characteristics of rapidly growing cells, that is, a high nucleus-to-cytoplasm ratio, prominent nucleoli, an increased frequency of mitotic cells, and relatively little specialized structure. The presence of invading cells in an otherwise normal tissue section is used to diagnose a malignancy.

Cancers Usually Originate in Proliferating Cells

In order for most oncogenic mutations to induce cancer, they must occur in dividing cells so that the mutation is passed on to many progeny cells. When such mutations occur in nondividing cells (e.g., neurons and muscle cells), they generally do not induce cancer, which is why tumors of muscle and nerve cells are rare in adults. Nonetheless, cancer can occur in tissues composed mainly of nondividing differentiated cells such as erythrocytes and most white blood cells, absorptive cells that line the small intestine, and keratinized cells that form the skin. The cells that initiate the tumors are not the differentiated cells, but rather their precursor cells. Fully differentiated cells usually do not divide. As they die or wear out, they are continually replaced by proliferation and differentiation of **stem cells**, and these cells are capable of transforming into tumor cells.

In Chapter 21, we learned that stem cells both perpetuate themselves and give rise to differentiating cells that can regenerate a particular tissue for the life of an organism (Figure 21-2). For instance, many differentiated blood cells have short life spans and are continually replenished from hematopoietic (blood-forming) stem cells in the bone marrow (Figure 21-15). Populations of stem cells in the intestine, liver, skin, bone, and other tissues likewise give rise to all or many of the cell types in these tissues, replacing aged and dead cells, by pathways analogous to hematopoiesis in bone marrow. Similarly within a tumor there may be only certain cells with the ability to divide uncontrollably and generate new tumors; such cells are *tumor stem cells*, discussed below.

Because stem cells can divide continually over the life of an organism, oncogenic mutations in their DNA can accumulate, eventually transforming them into cancer cells. Cells that have acquired these mutations have an abnormal proliferative capacity and generally cannot undergo normal processes of differentiation. Many oncogenic mutations, such as ones that prevent apoptosis or generate an inappropriate growth-promoting signal, also can occur in more differentiated, but still replicating, progenitor cells. Such mutations in hematopoietic progenitor cells can lead to various types of leukemia.

Cancer Stem Cells Can Be a Minority Population

Tumors may arise from normal stem cells. In addition, at least some types of tumor appear to have their own stem cells; that is, these are the only tumor cells capable of seeding a new tumor. The concept is that tumor cells are diverse, and among them some cells will cease dividing while others can continue cancerous growth. The latter, of course, are the most dangerous and the most important to destroy with anticancer treatments. Like normal stem cells, tumor stem cells divide to produce two daughters: another tumor stem cell and a cell with more limited replicative potential.

 One way to identify cancer stem cells is to purify different classes of cells from a tumor that carry different surface markers, usually using a fluorescent-activated cell sorter (FACS, see Chapter 9). Transplantation tests, usually with mice, reveal which classes of cell have the ability to seed a new tumor and which do not. For example, a few hundred human brain tumor cells with an antigen called *CD133* on the surface are potent in starting new tumors in immunologically deprived mice, whereas many thousands of non-*CD133* tumor cells were unable to seed tumors. Similar findings have been made for human multiple myeloma, where fewer than 5 percent of the cells lack a marker called *CD138*, and these cells have considerably greater ability than the rest of the cells to start tumor growth. Surface proteins on human breast cancer cells also allowed identification of a minority class of cells that carried with them most of the dangerous potential to form tumors. These findings suggest that identifying tumor stem cells and then targeting those cells specifically with drugs or antibodies may be a more effective cancer therapy than targeting bulk tumor cells. It is not yet clear how many types of tumors have stem cells that differ from the majority of cells. ■

The results with cancer stem cells highlight three important points. First, tumors are not made up of uniform cells, even if they originated from a single initiating cell. Second, a minority of the cells may be the really dangerous ones. Third, tumor cells may grow faster or slower depending on whether they find themselves in a particular environment. Just as stem cells can be kept in a dividing, nondifferentiating state by virtue of occupying a suitable niche (Chapter 21), tumor stem cells may behave according to their surroundings. Some neighboring cells may be conducive to tumor cell or tumor stem cell growth more than others. Figure 25-4 depicts normal stem-cell dependence on a niche (Figure 25-4a) and four scenarios in which cancer cells can originate and expand. Changes in niche cells, for example by mutation, can create a larger environment in which stem cells will reproduce themselves, in the worst case becoming cancer stem cells (Figure 25-4b). Alternatively, the prospective cancer stem cells can mutate and adjust to surviving and proliferating in a niche that is not normally their own (Figure 25-4c). In another scenario, stem cells become self-sufficient for growth, no longer requiring sustaining signals from niche cells (Figure 25-4d). Lastly, progenitor cells that normally have the ability to reproduce themselves for a period but not indefinitely become mutated in a way that makes them into cancer cells with large replicative potential (Figure 25-4e). In each case many of the cells that make up the tumor are not themselves able to divide indefinitely or seed new tumors.

The idea that *tumor microenvironment* matters extends to the importance of the extracellular matrix and to one of the most common environments for a tumor cell: inflammatory cells. Cancers frequently arise at sites of injury or infection. Immune cells migrate to sites of injury, growth factors are produced there to promote healing, and the extracellular matrix is reconstructed. All of these local tissue properties may contribute to the establishment and growth of a tumor.

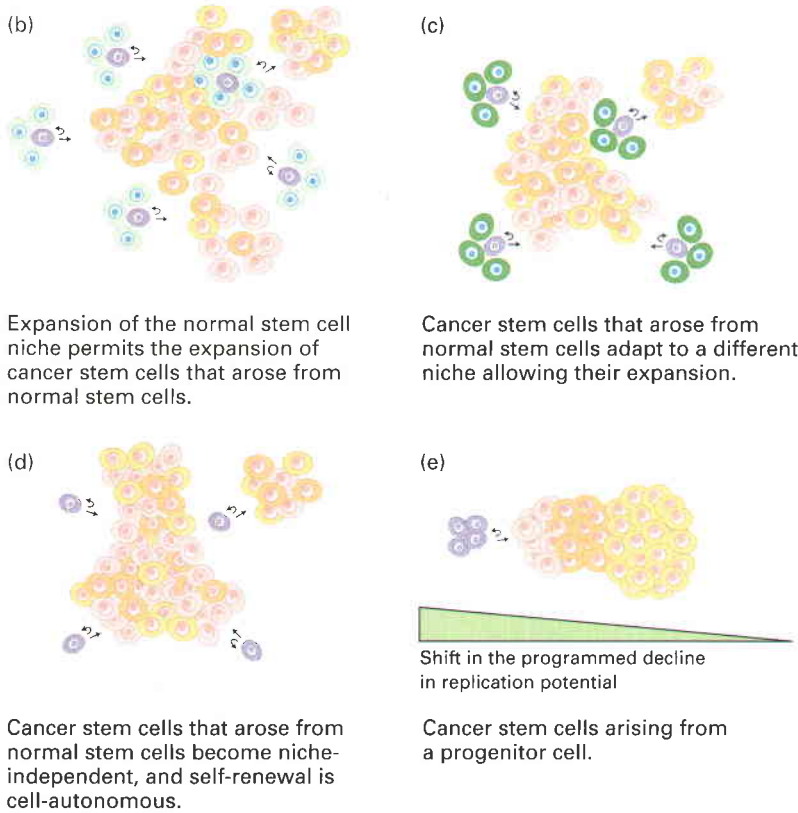

Tumor Growth Requires Formation of New Blood Vessels

Tumors, whether primary or secondary, require recruitment of new blood vessels in order to grow to a large mass. In the absence of a blood supply, a tumor can grow into a mass of about 10^6 cells, roughly a sphere 2 mm in diameter. At this point, division of cells on the outside of the tumor mass is balanced by death of those in the center owing to an inadequate supply of nutrients. Such tumors, unless they secrete hormones, cause few problems. However, most tumors induce the formation of new blood vessels that invade the tumor and nourish it, a process called *angiogenesis*. This complex process requires several discrete steps: degradation of the basement membrane that surrounds a nearby capillary, migration of endothelial cells lining the capillary into the tumor, division of these endothelial cells, and formation of a new basement membrane around the newly elongated capillary.

Many tumors produce growth factors that stimulate angiogenesis; other tumors somehow induce surrounding normal cells to synthesize and secrete such factors. Basic fibroblast growth factor (bFGF), transforming growth factor α (TGF α), and vascular endothelial growth factor (VEGF),

The dependence of normal stem cells on the niche limits their expansion.

◀ **FIGURE 25-4 Possible origins of cancer stem cells.** (a) Interactions between normal stem cells and supporting niche cells. In normal tissues, the niche cells (light green) provide signals enabling normal stem cells (blue) to reproduce themselves (curved arrow), while at the same time producing cells that go on to proliferate and then differentiate (pink). These progenitor cells (pink, orange, yellow) do not receive a signal from the niche, so they do not remain stem cells. With each cell division, the proliferation capacity of the progenitor cells declines. Panels (b), (c), (d), and (e) represent possible ways in which tumors may arise from normal stem cells by circumventing niche-dependent restrictions on stem-cell expansion. (b) Expansion of the stem-cell niche (pale green) allows a corresponding expansion of cancer stem cells (purple) that have arisen from normal stem cells. The expansion of niche cells may be driven by genetic alterations in the niche cells. (c) Alterations in cancer stem cells (purple) enable them to be sustained by alternative niche cells (dark green) to provide them with self-renewal signals. This mechanism could result in the invasion of local tissues or may facilitate cancer stem-cell growth at sites of metastasis. The resultant tumors are a mixture of cancer stem cells and their nontumorigenic progeny. (d) Genetic or epigenetic alterations in cancer stem cells enable them to become niche-independent such that they undergo cell-autonomous self-renewal. The resulting tumors containing self-renewing stem cells and their nontumorigenic progeny. (e) Mutations may arise that give progenitor cells the stem-cell property of self-renewal. This loss of growth control can lead to tumor formation. [Adapted from Clarke and Fuller, 2006, *Cell* 124:1111.]

which are secreted by many tumors, all have angiogenic properties. New blood vessels nourish the growing tumor, allowing it to increase in size and thus increase the probability that additional harmful mutations will occur. The presence of an adjacent blood vessel also facilitates the process of metastasis.

In humans there are five VEGF genes and three VEGF-receptor-protein genes. VEGF expression can be induced by hypoxia, starvation of cells for oxygen that occurs when $[pO_2] < 7$ mmHg. The VEGF receptors, which are tyrosine kinases, regulate different aspects of blood vessel growth

such as endothelial (blood vessel wall) cell survival and growth, cell migration, and vessel wall permeability.

The hypoxia signal is mediated by hypoxia-inducible factor (HIF-1), a transcription factor that is activated in conditions of low oxygen and then binds to and induces transcription of the VEGF gene and about 30 other genes, many of which can affect the probability of tumor growth. Among these are glycolytic enzymes such as lactate dehydrogenase; thus HIF-1 may also help tumor cells to adapt to low oxygen by turning to glycolysis rather than oxidative phosphorylation for ATP generation. HIF-1 activity is controlled, in turn, by an oxygen sensor

▲ EXPERIMENTAL FIGURE 25-5 Scanning electron micrographs reveal the organizational and morphological differences between normal and transformed 3T3 cells.

(a) Normal 3T3 cells are elongated and are aligned and closely packed in an orderly fashion. (b) 3T3 cells transformed by an oncogene encoded by Rous sarcoma virus are rounded and covered with small hairlike processes

composed of a prolyl hydroxylase that is active in normal O_2 levels but inactive when deprived of O_2 . Hydroxylation of HIF-1 causes ubiquitination and degradation of the transcription factor, a process that is blocked when O_2 is low.

 Several natural proteins that inhibit angiogenesis (e.g., angiogenin and endostatin) and antagonists of the VEGF receptor have excited much interest as potential therapeutic agents. Although new blood vessels are constantly forming during embryonic development, few form normally in adults except after injury. Thus specific inhibitors of angiogenesis might be effective against many kinds of tumors and have few adverse side effects. New drugs developed according to this rationale are showing promise. Drugs that inhibit the VEGF receptor tyrosine kinase activity are being tested. One recently approved is a monoclonal antibody against VEGF itself, which has been effective against metastatic colon cancer. One of the challenges in such therapies is to avoid an immune response directed against the monoclonal antibody. This is done by engineering changes in the mouse monoclonal antibody so it more closely matches human antibody sequences. Antibody and other anti-metastatic cancer treatments are typically successful in extending survival times for periods of months. It is hoped that combinations of treatments as well as new treatments will move closer to the real goal, complete cures. ■

Specific Mutations Transform Cultured Cells into Tumor Cells

The morphology and growth properties of tumor cells clearly differ from those of their normal counterparts; some of these differences are also evident when cells are cultured. That mutations cause these differences was conclusively established by transfection experiments with a line of cultured mouse fibroblasts called *3T3 cells*. These cells normally grow only when attached to the plastic surface of a culture

dish and are maintained at a low cell density. Because 3T3 cells stop growing when they contact other cells, they eventually form a monolayer of well-ordered cells that have stopped proliferating and are in the quiescent G_0 phase of the cell cycle (Figure 25-5a). When DNA from human bladder cancer cells is transfected into cultured 3T3 cells, about one cell in a million incorporates a particular segment of the exogenous DNA that causes a distinctive phenotypic change. The progeny of the affected cell are more rounded and less adherent to one another and to the dish than are the normal surrounding cells, forming a three-dimensional cluster of cells (a focus) that can be recognized under the microscope (Figure 25-5b). Such cells, which continue to grow when the normal cells have become quiescent, have undergone oncogenic **transformation**. The transformed cells have properties similar to those of malignant tumor cells, including changes in cell morphology, ability to grow unattached to an extracellular matrix, reduced requirement for growth factors, secretion of plasminogen activator, and loss of actin microfilaments.

Figure 25-6 outlines the procedure for transforming 3T3 cells with DNA from a human bladder cancer and cloning the specific DNA segment that causes transformation. It was remarkable to find a small piece of DNA with this capability; had more than one piece been needed, the experiment would have failed. Subsequent studies showed that the cloned segment included a mutant version of the cellular *ras* gene, where the glycine normally found in position 12 is replaced with a valine. This mutant was designated *ras^D*, where the “D” stands for dominant. The mutation is genetically **dominant** because the active protein has an effect even in the presence of the other, normal *ras* allele. Normal **Ras protein**, which participates in many intracellular signal-transduction pathways activated by growth factors (Chapter 16), cycles between an inactive, “off” state with bound GDP and an active, “on” state with bound GTP. The mutated Ras^D

◀ **EXPERIMENTAL FIGURE 25-6 Transformation of mouse cells with DNA from a human cancer cell permits identification and molecular cloning of the *ras^D* oncogene.** Addition of DNA from a human bladder cancer to a culture of mouse 3T3 cells causes about one cell in a million to divide abnormally and form a focus, or clone, of transformed cells. To clone the oncogene responsible for transformation, advantage is taken of the fact that most human genes have nearby repetitive DNA sequences called *Alu* sequences. DNA from the initial focus of transformed mouse cells is isolated, and the oncogene is separated from adventitious human DNA by secondary transfer to mouse cells. The adventitious DNA is human DNA that has no effect on cell transformation, but just happened to end up in a cell that also contains the active oncogene. The total DNA from a secondary transfected mouse cell is then cloned into bacteriophage λ ; only the phage that receives human DNA hybridizes with an *Alu* probe. The hybridizing phage should contain part of or all the transforming oncogene. This expected result can be proved by showing either that the phage DNA can transform cells (if the oncogene has been completely cloned) or that the cloned piece of DNA is always present in cells transformed by DNA transfer from the original bladder cancer donor cell.

protein hydrolyzes bound GTP very slowly and therefore accumulates in the active state, sending a growth-promoting signal to the nucleus even in the absence of the hormones normally required to activate its signaling function.

The production and **constitutive** activation of Ras^D protein is not sufficient to cause transformation of normal cells in a primary (fresh) culture of human, rat, or mouse fibroblasts. Unlike cells in a primary culture, however, cultured 3T3 cells have undergone loss-of-function mutations in the *p19ARF* or *p53* genes, which are regulators of the cell cycle. Such cells can grow for an unlimited time in culture if periodically diluted and supplied with nutrients, which normal cells cannot do (see Figure 9-31b). These immortal 3T3 cells are transformed into full-blown tumor cells only when they produce a constitutively active Ras protein or other oncoproteins. For this reason, transfection with the *ras^D* gene can transform 3T3 cells, but not normal cultured primary fibroblast cells, into tumor cells.

A mutant *ras* gene is found in most human colon, bladder, pancreatic, and other cancers, but not in normal human DNA; thus it must arise as the result of a somatic mutation in one of the tumor progenitor cells. Any gene, such as *ras^D*, that encodes a protein capable of transforming cells in culture or inducing cancer in animals is referred to as an oncogene. An oncogene arises from a normal cellular gene, a proto-oncogene, such as *ras*. The oncogenes carried by viruses that cause tumors in animals are often derived from proto-oncogenes that were hijacked from the host genome and altered to be oncogenic. When this was first discovered, it was startling to find that these dangerous viruses were turning the animal's own genes against them.

A Multi-hit Model of Cancer Induction Is Supported by Several Lines of Evidence

As noted earlier and illustrated by the oncogenic transformation of 3T3 cells, multiple mutations usually are required

to convert a normal body cell into a malignant one. According to this “multi-hit” model, evolutionary (or “survival of the fittest”) cancers arise by a process of clonal selection not unlike the selection of individual animals in a large population. Here is the scenario, which may or may not apply to all cancers: A mutation in one cell, perhaps a stem cell, would give it a slight growth advantage. One of the progeny cells would then undergo a second mutation that would allow its descendants to grow more uncontrollably and form a small benign tumor; a third mutation in a cell within this tumor would allow it to outgrow the others and overcome constraints imposed by the tumor microenvironment, and its progeny would form a mass of cells, each of which would have these three mutations. An additional mutation in one of these cells would allow its progeny to escape into the blood and establish daughter colonies at other sites, the hallmark of metastatic cancer. This model makes two easily testable predictions.

First, all the cells in a given tumor should contain at least some genetic alterations in common. Systematic analysis of cells from individual human tumors supports the prediction that all the cells are derived from a single progenitor. Recall that during the fetal life of a human female each cell inactivates one of the two X chromosomes. A woman is a genetic mosaic; half the cells have one X inactivated, and the remainder have the other X inactivated. If a tumor did not arise from a single progenitor, it would be composed of a mix of cells with one or the other X inactivated. In fact, the cells from a woman’s tumor have the same inactive X chromosome. Different tumors can be composed of cells with either the maternal or the paternal X inactive. Second, cancer incidence should increase with age because it can take decades for the required multiple mutations to occur. Assuming that the rate of mutation is roughly constant during a lifetime, then the incidence of most types of cancer would be independent of age if only one mutation were required to convert a normal cell into a malignant one. In fact current estimates suggest 5–6 “hits,” or mutations, must accumulate as the most dangerous cancer cells emerge. As the data in Figure 25-7 show, the incidence of many types of human cancer does indeed increase drastically with age.

More direct evidence that multiple mutations are required for tumor induction comes from transgenic mice. A variety of combinations of oncogenes can cooperate in causing cancer. For example, mice have been made that carry either the mutant *ras*^{V12} dominant oncogene (one version of *ras*^D) or the *c-myc* proto-oncogene, in each case under control of a mammary cell-specific promoter/enhancer from a retrovirus. The promoter is induced by endogenous hormone levels and tissue-specific regulators, leading to overexpression of *c-myc* or *ras*^{V12} in breast tissue. Heightened transcription of *c-myc* mimics previously identified oncogenic mutations that turn up *c-myc* transcription, converting the proto-oncogene into an oncogene. By itself, the *c-myc* transgene causes tumors only after 100 days, and then in only a few mice; clearly only a minute fraction of the mammary cells that overproduce the Myc protein become malignant. Similarly, production of the mutant Ras^{V12} protein

▲ **EXPERIMENTAL FIGURE 25-7** The incidence of human cancers increases as a function of age. The marked increase in the incidence with age is consistent with the multi-hit model of cancer induction. Note that the logarithm of annual incidence is plotted versus the logarithm of age. [From B. Vogelstein and K. Kinzler, 1993, *Trends Genet.* 9:101.]

alone causes tumors earlier but still slowly and with about 50 percent efficiency over 150 days. When the *c-myc* and *ras*^{V12} transgenics are crossed, however, such that all mammary cells produce both Myc and Ras^{V12}, tumors arise much more rapidly and all animals succumb to cancer (Figure 25-8). Such experiments emphasize the synergistic effects of multiple oncogenes. They also suggest that the long latency of tumor

▲ **EXPERIMENTAL FIGURE 25-8** The kinetics of tumor appearance in female mice carrying either one or two oncogenic transgenes shows the cooperative nature of multiple mutations in cancer induction. Each of the transgenes was driven by the mouse mammary tumor virus (MMTV) breast-specific promoter. The hormonal stimulation associated with pregnancy activates the MMTV promoter and hence the overexpression of the transgenes. The graph shows the time course of tumorigenesis in mice carrying either *myc* or *ras*^D transgenes as well as in the progeny of a cross of *myc* carriers with *ras*^D carriers that contain both transgenes. The results clearly demonstrate the cooperative effects of multiple mutations in cancer induction. [See E. Sinn et al., 1987, *Cell* 49:465.]

formation, even in the double-transgenic mice, is due to the need to acquire additional somatic mutations.

Similar cooperative effects between oncogenes can be seen in cultured cells. For example, transfection of normal fibroblasts (*not* partially transformed 3T3 fibroblasts) with either *c-myc* or activated *ras^D* is not sufficient for oncogenic transformation, whereas when transfected together, the two genes cooperate to transform the cells. Deregulated levels of *c-myc* alone induce proliferation but also sensitize fibroblasts to apoptosis, and overexpression of activated *ras^D* alone induces cells to go into a state where they can no longer divide, which is termed *senescence*. When the two oncogenes are expressed in the same cell, these negative cellular responses are neutralized and the cells undergo transformation. While the examples mentioned are combinations of oncogenes, it is also possible to enhance cancer rates or cultured cell transformations by combining an oncogene with loss of a tumor-suppressor gene.

Successive Oncogenic Mutations Can Be Traced in Colon Cancers

Studies on colon cancer provide the most compelling evidence to date for the multi-hit model of cancer induction. Surgeons can obtain fairly pure samples of many human cancers, but since the tumor is observed only at one time, its exact stage of progression cannot be easily determined. An exception is colon cancer, which evolves through distinct, well-characterized morphological stages. These intermediate stages—polyps, benign adenomas, and carcinomas—can be isolated by a surgeon, allowing mutations that occur in each of the morphological stages to be identified. Numerous studies show that colon cancer arises from a series of mutations that commonly occur in a well-defined order, providing strong support for the multi-hit model (Figure 25-9).

Invariably the first step in colon carcinogenesis involves loss of a functional *APC* (*adenomatous polyposis coli*) gene, resulting in formation of polyps (precancerous growths) on the inside of the colon wall. Not every colon cancer, however, acquires all the later mutations or acquires them in the order depicted in Figure 25-9. Thus different combinations of mutations may result in the same phenotype. Most of the cells in a polyp contain the same one or two mutations in the *APC* gene that result in its loss or inactivation; thus they are clones of the cell in which the original mutation occurred. *APC* is a tumor-suppressor gene, and both alleles of the *APC* gene must carry an inactivating mutation for polyps to form because cells with one wild-type *APC* gene express enough *APC* protein to function normally. Like most tumor-suppressor genes, *APC* encodes a protein that inhibits the progression of certain types of cells through the cell cycle. The *APC* protein does so by preventing the Wnt signal-transduction pathway (Chapter 16) from activating expression of proto-oncogenes including the *c-myc* gene. The absence of functional *APC* protein thus leads to inappropriate production of *Myc*, a transcription factor that induces expression of many genes required for the transition from the *G*₁ to the *S* phase of the cell cycle. Cells homozygous for *APC* mutations proliferate at a rate higher than normal and form polyps.

If one of the cells in a polyp undergoes another mutation, this time an activating mutation of the *ras* gene, its progeny divide in an even more uncontrolled fashion, forming a larger adenoma (see Figure 25-9). Mutational loss of a particular chromosomal region (the relevant gene is not yet known), followed by inactivation of the *p53* gene, results in the gradual loss of normal regulation and the consequent formation of a malignant carcinoma. While the four “hits” listed here are certainly crucial parts of the picture, there may be additional contributing genetic events.

About half of all human tumors carry mutations in the *p53* tumor-suppressor gene, which encodes a key stress-response transcriptional regulator. Activity of *p53* causes cells in trouble to go into cell-cycle arrest or apoptosis. A critical feature of cell-cycle control is the *G*₁ checkpoint, which prevents cells with damaged DNA from entering *S* phase (Figure 20-35, 4a). The **p53 protein** is a sensor essential for the checkpoint control that arrests cells with damaged DNA in *G*₁. The arrest can be temporary, allowing correction of cell defects, or permanent, resulting in cell senescence. The *p53* protein has several functions, and which of them is most relevant to its tumor-suppressing function remains unclear. For example, a mutant *p53* protein that is unable to activate transcription can nonetheless suppress tumor formation. Virtually all *p53* mutations abolish its ability to bind to specific DNA sequences and activate gene expression.

DNA from different human colon carcinomas generally contains mutations in all four genes—loss-of-function mutations in the tumor suppressors *APC* and *p53*, and in the as-yet mysterious gene, and an activating (gain-of-function) mutation in the dominant oncogene *K-ras* (one of the *ras* family of genes)—establishing that multiple mutations in the same cell are needed for the cancer to form. Some of these mutations appear to confer growth advantages at an early stage of tumor development, whereas other mutations promote the later stages, including invasion and metastasis, which are required for the malignant phenotype. The number of mutations needed for colon cancer progression may at first seem surprising, seemingly an effective barrier to tumorigenesis. Our genomes, however, are under constant assault. Recent estimates indicate that sporadically arising polyps have about 11,000 genetic alterations in each cell, though very likely only a few of these are relevant to oncogenesis. Genetic instability is a hallmark of cancer cells.

Colon carcinoma provides an excellent example of the multi-hit mode of cancer. The degree to which this model applies to cancer generally is only now being learned, but it is clear that many types of cancer each involve multiple mutations.

DNA Microarray Analysis of Expression Patterns Can Reveal Subtle Differences Between Tumor Cells

Traditionally the properties of tumor and normal cells have been assessed by staining and microscopy. The prognosis for many tumors could be determined, within certain limits,

◀ **FIGURE 25-9 The development and metastasis of human colorectal cancer and its genetic basis.** A mutation in the *APC* tumor-suppressor gene in a single epithelial cell causes the cell to divide, although surrounding cells do not, forming a mass of localized benign tumor cells, or polyp. Subsequent mutations leading to expression of a constitutively active *Ras* protein and loss of two tumor-suppressor genes—an unidentified gene on chromosome 18 and *p53*—generate a malignant cell carrying all four mutations. The loss of the tumor-suppressor gene on chromosome 18 arises from a deletion that includes the *DCC* (*deleted in colorectal cancer*) gene. It is not clear that this particular gene is in fact the important gene with respect to cancer, but something in that vicinity serves as a tumor suppressor. This cell continues to divide, and the progeny invade the basement membrane that surrounds the tissue. Some tumor cells spread into blood vessels that will distribute them to other sites in the body. Additional mutations permit the tumor cells to exit from the blood vessels and proliferate at distant sites; a patient with such a tumor is said to have cancer. [Adapted from B. Vogelstein and K. Kinzler, 1993, *Trends Genet.* 9:101.]

from their histology. However the appearance of cells alone has limited information content, and better ways to discern the properties of cells are desirable both to understand tumorigenesis and to arrive at meaningful and accurate decisions about prognosis and therapy.

As we've seen, genetic studies can identify the single initiating mutation or series of mutations that cause transformation of normal cells into tumor cells, as in the case of colon cancer. After these initial events, however, the cells of a tumor undergo a cascade of changes reflecting the interplay

between the initiating events and signals from outside. As a result, tumor cells can become quite different, even if they arise from the same initiating mutation or mutations. Although these differences may not be recognized from the appearance of cells, they can be detected from the cells' patterns of gene expression. DNA microarray analysis can determine the expression of tens of thousands of genes simultaneously, permitting complex phenotypes to be defined at the molecular genetic level. (See Figures 5-29 and 5-30 for an explanation of this technique.)

The advent of DNA microarray technology is allowing more detailed examination of tumor properties. Not surprisingly, primary tumors can often be distinguishable from metastatic tumors by the pattern of gene expression. More interestingly, a subset of solid primary tumors has been found to have characteristics more typical of metastatic tumors, suggesting that it may be possible to identify primary tumors that have a greater probability of becoming metastatic. This also raises the possibility that, at least for some types of cancer, the initiating events of the pri-

mary tumor may set a course toward metastasis. This hypothesis can be distinguished from the scenario of the emergence of a rare subset of cells within the primary tumor acquiring a series of further mutations that are necessary for metastasis.

FIGURE 25-10 Microarray analysis recently has been applied to diffuse large B cell lymphoma, a disease marked by the presence of abnormally large B lymphocytes throughout lymph nodes. Affected patients have highly variable outcomes, so the disease has long been suspected to be, in fact, multiple diseases. Microarray analysis of lymphomas from different patients revealed two groups distinguished by their patterns of gene expression (Figure 25-10). No morphological or visible criteria were found that could distinguish the two types of tumors. Patients with one tumor type defined by the microarray data survived much longer than those with the other type. Lymphomas whose gene expression is similar to that of B lymphocytes in the earliest stages of differentiation have a better prognosis; lymphomas

◀ **EXPERIMENTAL FIGURE 25-10 Differences in gene expression patterns determined by DNA microarray analysis can distinguish between otherwise phenotypically similar lymphomas.** Samples of mRNA were extracted from normal lymphocytes at different stages of differentiation and from malignant lymphocytes obtained from patients with three types of lymphoma. DNA microarray analysis of the extracted RNA determined the transcription levels of about 18,000 genes in each of the 96 experimental samples of normal and malignant lymphocytes. (See Figures 5-29 and 5-30 for description of microarray analysis.) In this cluster diagram, each vertical column contains the data for a particular lymphocyte sample (see sample key), and each horizontal row contains data for a single gene. The cluster diagram includes the data from only a selected set of the 18,000 genes, the ones whose expression differs the most in the various lymphocyte samples. An intense red color indicates a high level of transcription of that gene; intense green indicates the opposite. The genes were grouped according to their similar patterns of hybridization. For example, genes indicated by the green bar on the right are active in proliferating cells, such as transformed cultured cells (pink bar at top) or diffuse large B cell lymphoma cells (dark blue bar at top). Genes indicated by the red and blue bars on the right are active in T cells and activated B cells, respectively. The different cell samples along the top of the diagram also were grouped according to their similar expression patterns. The resulting dendrogram (tree diagram) shows that the samples from patients with diffuse large B cell lymphoma (dark blue samples) fall into two groups (black bars 1 and 2). One group is similar to relatively undifferentiated B lymphocytes in germinal centers (orange samples); the other is similar to more differentiated B cells (gray samples). [From A. A. Alizadeh et al., 2000, *Nature* 403:505.]

whose gene expression is closer to that of more differentiated B lymphocytes have a worse prognosis. Similar analyses of the gene expression patterns, or “signatures,” of other tumors are likely to improve classification and diagnosis, allowing informed decisions about treatments, and also to provide insights into the properties of tumor cells. ■

KEY CONCEPTS OF SECTION 25.1

Tumor Cells and the Onset of Cancer

- Cancer is a fundamental aberration in cellular behavior, touching on many aspects of molecular cell biology. Most cell types of the body can give rise to malignant tumor (cancer) cells.
- Cancer cells can multiply in the absence of at least some of the growth-promoting factors required for proliferation of normal cells and are resistant to signals that normally program cell death (apoptosis).
- Most oncogenic mutations occur in somatic cells and are not carried in the germ-line DNA.
- Cancer cells sometimes invade surrounding tissues, often breaking through the basement membranes that define the boundaries of tissues and spreading through the body to establish secondary areas of growth, a process called *metastasis*. Metastatic tumors often secrete proteases, which degrade the surrounding extracellular matrix (Figure 25-3).
- Cancer cells may arise from stem cells and often arise from proliferating cells. Cancer cells bear more resemblance to dividing precursor cells than to more mature differentiated cell types.
- Both primary and secondary tumors require angiogenesis, the formation of new blood vessels, in order to grow to a large mass.
- Certain cultured cells transfected with tumor-cell DNA undergo transformation (see Figure 25-6). Such transformed cells share certain properties with tumor cells.
- The multi-hit model, which proposes that multiple mutations are needed to cause cancer, is consistent with the genetic homogeneity of cells from a given tumor, the observed increase in the incidence of human cancers with advancing age, and the cooperative effect of oncogenic transgenes and tumor-suppressor gene mutations on tumor formation in mice.
- Colon cancer develops through distinct morphological stages that commonly are associated with mutations in specific tumor-suppressor genes and proto-oncogenes (see Figure 25-9).
- DNA microarray analysis can identify differences in gene expression between types of tumor cells that are indistinguishable by traditional criteria. Some tumor cells appear to be related to specific types of normal cells at certain stages of development based on similarities in their expression patterns.

- Within tumors, subsets of cells can be identified with distinctive gene expression characteristics. These differences may allow identification of dangerous tumor stem cells among a mass of cells with limited replicative or metastatic potential.

25.2 The Genetic Basis of Cancer

As we have noted, mutations in three broad classes of genes—proto-oncogenes (e.g., *ras*), tumor-suppressor genes (e.g., *APC*), and caretaker genes—play key roles in cancer induction. These genes encode many kinds of proteins that help control cell growth and proliferation (Figure 25-11). Virtually all human tumors have inactivating mutations in genes whose products normally act at various cell-cycle **checkpoints** to stop a cell’s progress through the cell cycle if a previous step has occurred incorrectly or if DNA has been damaged. For example, most cancers have inactivating mutations in the genes coding for one or more proteins that normally restrict progression through the G₁ stage of the cell cycle, or activating mutations in genes coding for proteins that drive the cells through the cell cycle. Likewise, a constitutively active Ras or other activated signal-transduction protein is found in several kinds of human tumor that have different origins. Thus malignancy and the intricate processes for controlling the cell cycle discussed in Chapter 20 are two faces of the same coin. In the series of events leading to growth of a tumor, oncogenes combine with tumor-suppressor mutations to give rise to the full spectrum of tumor-cell properties described in the previous section (see Figure 25-9).

In this section, we consider the general types of mutations that are oncogenic and see how certain viruses can cause cancer. We also explain why some inherited mutations increase the risk for particular cancers and consider the relation between cancer and developmentally important genes.

Gain-of-Function Mutations Convert Proto-oncogenes into Oncogenes

Recall that an oncogene is any gene that encodes a protein able to transform cells in culture, usually in combination with other cell alterations, or to induce cancer in animals. Of the many known oncogenes, all but a few are derived from normal cellular genes (i.e., proto-oncogenes) whose wild-type products promote cell proliferation or other features important for cancer. For example, the *ras* gene discussed previously is a proto-oncogene that encodes an intracellular signal-transduction protein; the mutant *ras^D* gene derived from *ras* is an oncogene, whose encoded protein provides an excessive or uncontrolled growth-promoting signal. Other proto-oncogenes encode growth-promoting signal molecules and their receptors, anti-apoptotic (cell-survival) proteins, and some transcription factors.

Conversion, or activation, of a proto-oncogene into an oncogene generally involves a *gain-of-function* mutation. At

▲ **FIGURE 25-11 Seven types of proteins that participate in controlling cell growth and proliferation.** Cancer can result from expression of mutant forms of these proteins. Mutations changing the structure or expression of proteins that normally promote cell growth generally give rise to dominantly active oncogenes. Many, but not all, extracellular signaling molecules (I), signal receptors (II), signal-transduction proteins (III), and transcription factors (IV) are in this category. Cell-cycle control proteins (V) that function to restrain

cell proliferation and DNA-repair proteins (VI) are encoded by tumor-suppressor genes. Mutations in these genes act recessively, greatly increasing the probability that the mutant cells will become tumor cells or that mutations will occur in other classes. Apoptotic proteins (VII) include tumor suppressors that promote apoptosis and oncoproteins that promote cell survival. Virus-encoded proteins that activate signal receptors (Ia) also can induce cancer.

least four mechanisms can produce oncogenes from the corresponding proto-oncogenes:

1. *Point mutation* (i.e., change in a single base pair) in a proto-oncogene that results in a hyperactive or constitutively active protein product
2. *Chromosomal translocation* that fuses two genes together to produce a hybrid gene encoding a chimeric protein whose activity, unlike that of the parent proteins, often is constitutive
3. *Chromosomal translocation* that brings a growth-regulatory gene under the control of a different promoter that causes inappropriate expression of the gene
4. *Amplification* (i.e., abnormal DNA replication) of a DNA segment including a proto-oncogene, so that numerous copies exist, leading to overproduction of the encoded protein

An oncogene formed by either of the first two mechanisms encodes an “oncoprotein” that differs from the normal protein encoded by the corresponding proto-oncogene. In contrast, the other two mechanisms generate oncogenes whose protein products are identical with the normal proteins; their oncogenic effect is due to production at higher-than-normal levels or in cells where they normally are not produced. The localized amplification of DNA to produce as many as 100 copies of a given region (usually a region spanning hundreds of kilobases) is a common genetic change seen in tumors. Normally such an event would be repaired or the cell would stop cycling owing to checkpoint control, so such lesions imply a DNA-repair (caretaker) defect of some kind. This anomaly may take either of two forms: the duplicated DNA may be tandemly organized at a single site on a chromosome, or it may exist as small, independent mini-chromosome-like structures. The former case leads to a homogeneously staining region (HSR) that is visible in the light microscope at the site of the

▲ EXPERIMENTAL FIGURE 25-12 DNA amplifications in stained chromosomes take two forms, visible under the light microscope.

(a) Homogeneously staining regions (HSRs) in a human chromosome from a neuroblastoma cell. The chromosomes are uniformly stained with a blue dye so that all can be seen. Specific DNA sequences were detected using fluorescent in situ hybridization (FISH) in which fluorescently labeled DNA clones are hybridized to denatured DNA in the chromosomes. The chromosome 4 pair is marked (red) by in situ hybridization with a large DNA clone containing the *N-myc*

oncogene. On one of the chromosome 4's an HSR is visible (green) after staining for a sequence enriched in the HSR. (b) Optical sections through nuclei from a human neuroblastoma cell that contain so-called double-minute chromosomes. The normal chromosomes are the green and blue structures; the double-minute chromosomes are the many small red dots. Arrows indicate double-minutes associated with the surface or interior of the normal chromosomes. [From I. Solovei et al., 2000, *Genes Chromosomes Cancer* **29**:297–308, figs. 4 and 17.]

amplification; the latter case causes extra “minute” chromosomes, separate from the normal chromosomes that pepper a stained chromosomal preparation (Figure 25-12).

 Gene amplification may involve a small number of genes, such as the *N-myc* gene and its neighbor *DDX1*, which are amplified in neuroblastoma, or a chromosome region containing many genes. It can be difficult to determine which genes are amplified, a first step in determining which gene caused the tumor. DNA microarrays offer a powerful approach for finding amplified regions of chromosomes. Rather than look at gene expression, the application of microarrays described previously here and in Chapter 5, these experiments involve looking for abnormally abundant DNA sequences. Genomic DNA from cancer cells is used to probe arrays containing fragments of genomic DNA, and spots with amplified DNA give stronger signals than control spots. Among the amplified genes, the strongest candidates for the relevant ones can be identified by also measuring gene expression. A breast carcinoma cell line, with four known amplified chromosome regions, was screened for amplified genes, and the expression levels of those genes were also studied on microarrays. Fifty genes were found to be amplified, but only five were also highly expressed. These five were better candidates for being new oncogenes, since amplified genes that are not highly expressed are less likely to contribute to tumor growth. ■

However they arise, the gain-of-function mutations that convert proto-oncogenes to oncogenes are genetically dominant;

that is, mutation in only one of the two alleles is sufficient for induction of cancer. See Table 25-1 for a comparison of different classes of cancer-related genes.

Cancer-Causing Viruses Contain Oncogenes or Activate Cellular Proto-oncogenes

Pioneering studies by Peyton Rous beginning in 1911 led to the initial recognition that a virus could cause cancer when injected into a suitable host animal. Many years later molecular biologists showed that Rous sarcoma virus (RSV) is a retrovirus whose RNA genome is reverse-transcribed into DNA, which is incorporated into the host-cell genome (see Figure 4-49). In addition to the “normal” genes present in all retroviruses, oncogenic transforming viruses like RSV contain an oncogene: in the case of RSV, the *v-src* gene. Subsequent studies with mutant forms of RSV demonstrated that only the *v-src* gene, not the other viral genes, was required for cancer induction.

In the late 1970s, scientists were surprised to find that normal cells from chickens and other species contain a gene that is closely related to the RSV *v-src* gene. This normal cellular gene, a proto-oncogene, commonly is distinguished from the viral gene by the prefix “c” (*c-src*). RSV and other acutely transforming viruses are thought to have arisen by incorporating, or transducing, a normal cellular proto-oncogene into their genome. Subsequent mutation in the transduced gene then converted it into a dominantly acting oncogene, which can induce cell transformation even in the presence of the normal *c-src* proto-oncogene. Such viruses

TABLE 25-1 Classes of Genes Implicated in the Onset of Cancer

	NORMAL FUNCTION OF GENES	EXAMPLES OF GENE PRODUCTS	EFFECT OF MUTATION	GENETIC PROPERTIES OF MUTANT GENE	ORIGIN OF MUTATIONS
Proto-oncogenes	Promote cell survival or proliferation	Anti-apoptotic proteins, components of signaling and signal transduction pathways that result in proliferation, transcription factors	Gain-of-function mutations allow unregulated cell proliferation and survival	Mutations are genetically dominant	Arise by point mutation, chromosomal translocation, amplification
Tumor-suppressor genes	Inhibit cell survival or proliferation	Apoptosis-promoting proteins, inhibitors of cell-cycle progression, checkpoint-control proteins that assess DNA/chromosomal damage, components of signal pathways that restrain cell proliferation	Loss-of-function mutations allow unregulated cell proliferation and survival	Mutations are genetically recessive	Arise by deletion, point mutation, methylation
Caretaker genes	Repair or prevent DNA damage	DNA-repair enzymes	Loss-of-function mutations allow mutations to accumulate	Mutations are genetically recessive	Arise by deletion, point mutation, methylation

are called *transducing retroviruses* because their genomes contain an oncogene derived from a transduced cellular proto-oncogene.

Because its genome carries the potent *v-src* oncogene, the transducing RSV induces tumors within days. In contrast, most oncogenic retroviruses induce cancer only after a period of months or years. The genomes of these *slow-acting retroviruses*, which are weakly transforming, differ from those of transducing viruses in one crucial respect: they lack an oncogene. All slow-acting, or “long-latency,” retroviruses appear to cause cancer by integrating into the host-cell DNA near a cellular proto-oncogene and activating its expression. The long terminal repeat (LTR) sequences in integrated retroviral DNA can act as an enhancer or promoter for a nearby cellular gene, thereby stimulating its transcription. For example, in the cells from tumors caused by avian leukosis virus (ALV), the retroviral DNA is inserted near the *c-myc* gene. These cells overproduce c-Myc protein; as noted earlier, overproduction of c-Myc causes abnormally rapid proliferation of cells. Slow-acting viruses act slowly for two reasons: integration near a cellular proto-oncogene (e.g., *c-myc*) is a random, rare event, and additional mutations have to occur before a full-fledged tumor becomes evident.

In natural bird and mouse populations, slow-acting retroviruses are much more common than oncogene-containing retroviruses such as Rous sarcoma virus. Thus, insertional proto-oncogene activation is probably the

major mechanism by which retroviruses cause cancer. Although the only retrovirus known to cause human tumors is human T cell leukemia/lymphoma virus (HTLV), the huge investment in studying retroviruses as a model for human cancer paid off both in the discovery of cellular oncogenes and in the sophisticated understanding of retroviruses, which later accelerated progress on the HIV virus that causes AIDS.

A few DNA viruses also are oncogenic. Unlike most DNA viruses that infect animal cells (see Chapter 4), oncogenic DNA viruses integrate their viral DNA into the host-cell genome. The viral DNA contains one or more oncogenes, which permanently transform infected cells. For example, many warts and other benign tumors of epithelial cells are caused by the DNA-containing human papillomaviruses (HPV). A medically much more serious outcome of HPV infection is cervical cancer, the third most common type of cancer in women after lung and breast cancer; we shall examine HPV oncoproteins later in the chapter. The Pap smear, which is used to sample the cervical tissue and screen for possible cancers, is thought to have reduced the death rate by about 70 percent. However thousands of people still die from cervical cancer each year, and some of these deaths would have been prevented had screening been done. Fortunately, not all HPV infections lead to cancer. Unlike retroviral oncogenes, which are derived from normal cellular genes and have no function for the virus except to allow their proliferation in tumors, the known

oncogenes of DNA viruses are integral parts of the viral genome and are required for viral replication. As discussed later, the oncoproteins expressed from integrated viral DNA in infected cells act in various ways to stimulate cell growth and proliferation.

Loss-of-Function Mutations in Tumor-Suppressor Genes Are Oncogenic

Tumor-suppressor genes generally encode proteins that in one way or another inhibit cell proliferation. *Loss-of-function* mutations in one or more of these “brakes” contribute to the development of many cancers. Prominent among the classes of proteins encoded by tumor-suppressor genes are these five:

1. Intracellular proteins that regulate, or inhibit progression through, a specific stage of the cell cycle (e.g., p16 and Rb for G₁)
2. Receptors or signal transducers for secreted hormones or developmental signals that inhibit cell proliferation (e.g., TGFβ, the hedgehog receptor patched)
3. Checkpoint-control proteins that arrest the cell cycle if DNA is damaged or if chromosomes are abnormal (e.g., p53)
4. Proteins that promote apoptosis
5. Enzymes that participate in DNA repair, encoded by caretaker genes

Since generally one copy of a tumor-suppressor gene suffices to control cell proliferation, *both* alleles of a tumor-suppressor gene must be lost or inactivated in order to promote tumor development. Thus oncogenic loss-of-function mutations in tumor-suppressor genes are often genetically *recessive* (Table 25-1). In this context “recessive” means that if there is even one working gene, producing about half the usual amount of protein product, tumor formation will be prevented. With some genes, half the amount of product is not enough, in which case the loss of just one of the two genes can lead to cancer. This kind of gene is *haplo-insufficient*. The loss of one copy of the gene is decisive for the final phenotype, so this type of mutation is dominant. It is useful to remember, then, two processes by which cancer genes can be dominant: (1) loss of one copy of a tumor-suppressor gene, resulting in insufficient product to control growth, and (2) activation of a gene or protein that causes growth even in the presence of one normal allele, i.e., a dominant oncogene (as was described in the previous section). In many cancers, tumor-suppressor genes have deletions or point mutations that prevent production of any protein or lead to production of a nonfunctional protein. Another mechanism for inactivating tumor-suppressor genes is methylation of cytosine residues in the promoter or other control elements, which inhibits their transcription. Such methylation is commonly found in nontranscribed regions of DNA (see Chapter 7).

Inherited Mutations in Tumor-Suppressor Genes Increase Cancer Risk

Individuals with inherited mutations in tumor-suppressor genes have a hereditary predisposition for certain cancers. Such individuals generally inherit a germ-line mutation in one allele of the gene; somatic mutation of the second allele facilitates tumor progression. A classic case is retinoblastoma, which is caused by loss of function of *RB*, the first tumor-suppressor gene to be identified. As we discuss later, the protein encoded by *RB* helps regulate progress through the cell cycle.

Hereditary versus Sporadic Retinoblastoma Children with hereditary retinoblastoma inherit a single defective copy of the *RB* gene, sometimes seen as a small deletion on one of the copies of chromosome 13. The children develop several retinal tumors early in life and generally in both eyes. The deletion or mutation of the normal *RB* gene on the other chromosome is an essential step in tumor formation, giving rise to a cell that produces no functional Rb protein (Figure 25-13). Individuals with sporadic retinoblastoma, in contrast, inherit two normal *RB* alleles, each of which has undergone a loss-of-function somatic mutation in a single retinal cell. Because losing two copies of the *RB* gene is far less likely than losing one, sporadic retinoblastoma is rare and usually affects only one eye. However, *RB* mutation contributes to many tumors, and while the hereditary

(a) Hereditary retinoblastoma

(b) Sporadic retinoblastoma

▲ FIGURE 25-13 Role of spontaneous somatic mutation in retinoblastoma. This disease is marked by retinal tumors that arise from cells carrying two mutant *RB*⁻ alleles. (a) In hereditary (familial) retinoblastoma, a child inherits a normal *RB*⁺ allele from one parent and a mutant *RB*⁻ allele from the other parent. A single mutation in a heterozygous somatic retinal cell that inactivates the normal allele will produce a cell lacking any Rb gene function due to two mutations. (b) In sporadic retinoblastoma, a child inherits two normal *RB*⁺ alleles. Two separate somatic mutations in a particular retinal cell or its progeny are required to produce a homozygous *RB*⁻/*RB*⁻ cell.

retinoblastoma cases number about 100 per year in the U.S., about 100,000 other cancer cases each year involve RB mutations acquired postconception.

If retinal tumors are removed before they become malignant, children with hereditary retinoblastoma often survive until adulthood and produce children. Because their germ cells contain one normal and one mutant *RB* allele, these individuals will, on average, pass on the mutant allele to half their children and the normal allele to the other half. Children who inherit the normal allele are normal if their other parent has two normal *RB* alleles. However, those who inherit the mutant allele have the same enhanced predisposition to develop retinal tumors as their affected parent, even though they inherit a normal *RB* allele from their other, normal parent. Thus the *tendency* to develop retinoblastoma is inherited as a dominant trait; one mutant copy is sufficient to predispose a person to develop the cancer. As we shall see shortly, many human tumors (not just retinal tumors) contain mutant *RB* alleles or mutations affecting other components of the same pathway; most of these arise as the result of somatic mutations.

Inherited Forms of Colon and Breast Cancer Similar hereditary predisposition for other cancers has been associated with inherited mutations in other tumor-suppressor genes. For example, individuals who inherit a germ-line mutation in one *APC* allele develop thousands of precancerous intestinal polyps (see Figure 25-9). Since there is a high probability that one or more of these polyps will progress to malignancy, such individuals have a greatly increased risk for developing colon cancer before the age of 50. Screening for polyps by colonoscopy is a good idea for people 50 or older, even when no *APC* mutation is known to be present. Likewise, women who inherit one mutant allele of *BRCA-1*, another tumor-suppressor gene, have a 60 percent probability of developing breast cancer by age 50, whereas those who inherit two normal *BRCA-1* alleles have a 2 percent probability of doing so. Heterozygous *BRCA-1* mutations also increase the lifetime risk of ovarian cancer from 2 percent to 15–40 percent. *BRCA-1* protein is involved in repairing radiation-induced DNA damage and may also have other functions. In women with hereditary breast cancer, loss of the second *BRCA-1* allele, together with other mutations, is required for a normal breast duct cell to become malignant. However, *BRCA-1* generally is not mutated in sporadic, noninherited breast cancer.

Loss of Heterozygosity Clearly, then, we can inherit a propensity to cancer by receiving a damaged allele of a tumor-suppressor gene from one of our parents; that is, we are heterozygous for the mutation. That in itself typically will not cause cancer; since the remaining normal allele prevents aberrant growth, the cancer is recessive. Subsequent loss or inactivation of the normal allele in a somatic cell, referred to as *loss of heterozygosity (LOH)*, is usually how a cancer develops. One common mechanism for LOH involves missegregation during mitosis of the chromosomes bearing the

affected tumor-suppressor gene (Figure 25-14a). This process, also referred to as *nondisjunction*, is caused by failure of the spindle-assembly checkpoint, which normally prevents a metaphase cell with an abnormal mitotic spindle from completing mitosis (see Figure 20-35, 2). Another possible mechanism for LOH is mitotic recombination between a chromatid bearing the wild-type allele and a homologous chromatid bearing a mutant allele. As illustrated in Figure 25-14b, subsequent chromosome segregation can generate a daughter cell that is homozygous for the mutant tumor-suppressor allele. A third mechanism is the deletion or mutation of the normal copy of the tumor-suppressor gene; such a deletion can encompass a large chromosomal region and need not be a precise deletion of just the tumor-suppressor gene.

Estimates vary, but hereditary cancers, i.e., cancers that arise due in part to an inherited version of a gene, are thought to constitute about 10 percent of human cancers. Further work tracing contributions of human genes seems likely to increase the percentage. It is important to remember, however, that the inherited germ-line mutation alone is not sufficient to cause tumor development. In all cases, not only must the inherited normal tumor-suppressor allele be lost or inactivated, but mutations affecting other genes also are necessary for cancer to develop. Thus a person with a recessive tumor-suppressor gene mutation can be exceptionally susceptible to environmental mutagens such as radiation.

Aberrations in Signaling Pathways That Control Development Are Associated with Many Cancers

During normal development secreted signals such as Wnt, TGF β , and Hedgehog (Hh) are frequently used to direct cells to particular developmental fates, which may include the property of rapid mitosis. The effects of such signals must be regulated so that growth is limited to the right time and place. Among the mechanisms available for reining in the effects of powerful developmental signals are inducible intracellular antagonists, receptor blockers, and competing signals (Chapter 22). Mutations that prevent such restraining mechanisms from operating are likely to be oncogenic, causing inappropriate or cancerous growth.

Hh signaling, which is used repeatedly during development to control cell fates, is a good example of a signaling pathway implicated in cancer induction. In the skin and cerebellum, one of the human Hh proteins, Sonic hedgehog, stimulates cell division by binding to and inactivating a membrane protein called Patched1 (Ptc1) (see Figure 16-34). Loss-of-function mutations in *ptc1* permit cell proliferation in the absence of an Hh signal; thus *ptc1* is a tumor-suppressor gene. People who inherit a single working copy of *ptc1* have a propensity to develop skin and brain cancer; either can occur when the remaining allele is damaged. Other people can get these diseases, too, if they suffer loss of both copies of the gene. Thus there are both familial (inherited) and sporadic (noninherited) cases of these diseases, just as in retinoblastoma. Mutations in other genes in the Hh signaling pathway are also associated with cancer.

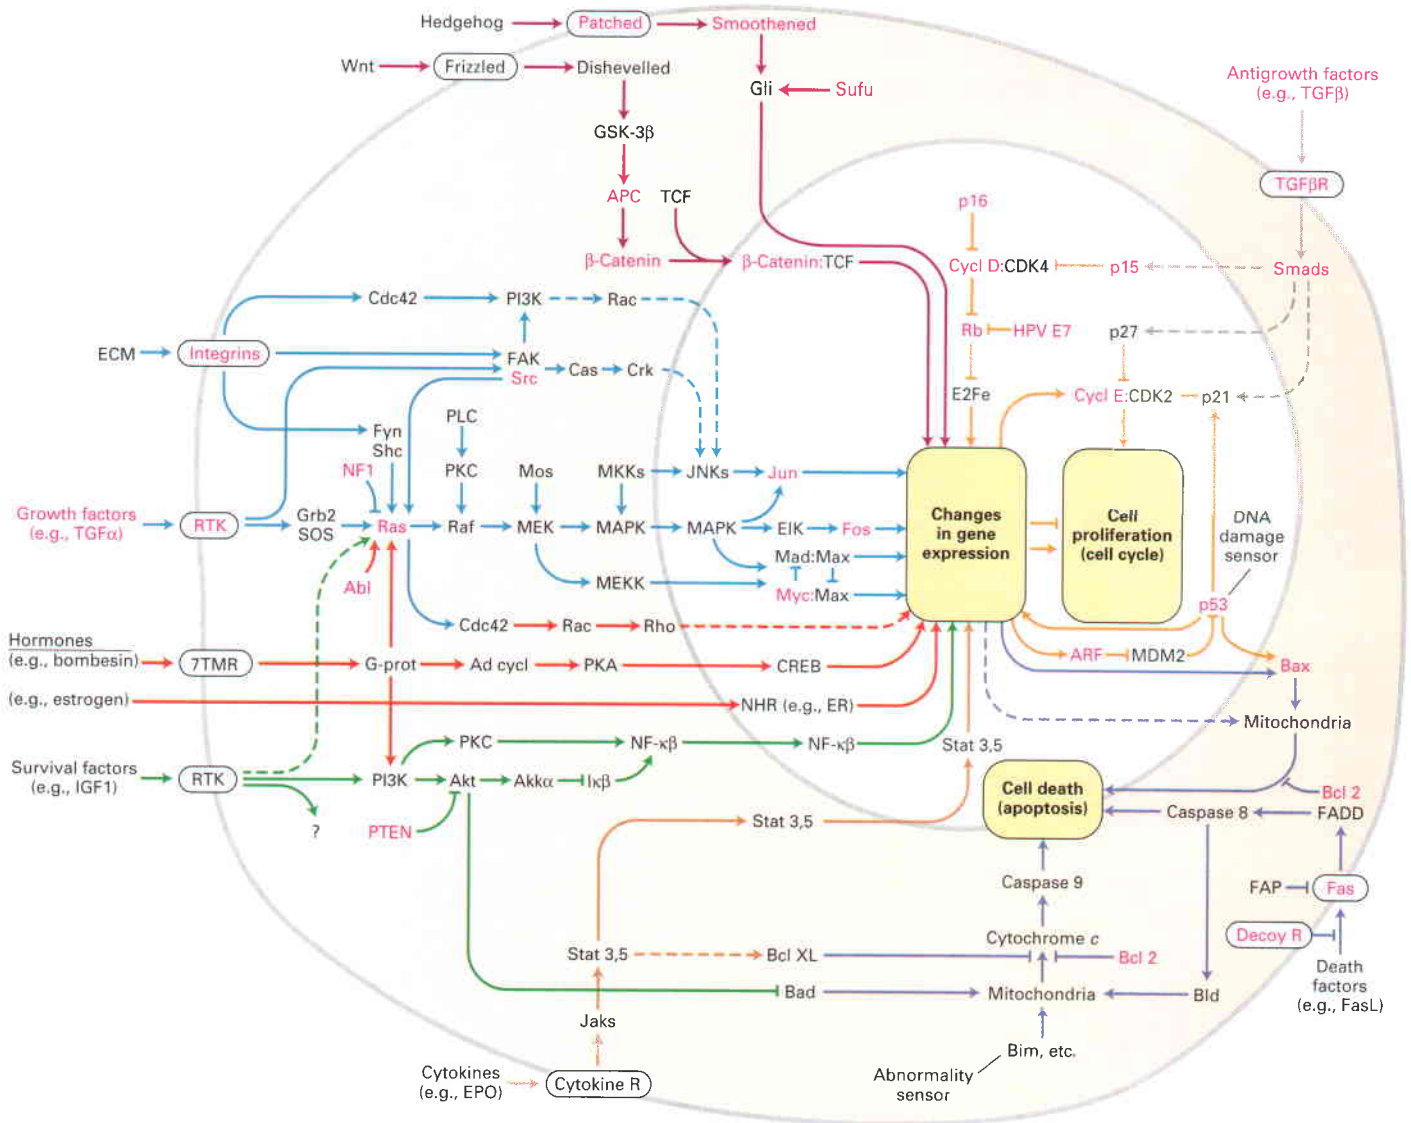

▲ FIGURE 25-14 Two mechanisms for loss of heterozygosity (LOH) of tumor-suppressor genes. A cell containing one normal and one mutant allele of a tumor-suppressor gene is generally phenotypically normal. (a) If formation of the mitotic spindle is defective, then the duplicated chromosomes bearing the normal and mutant alleles may segregate in an aberrant 3:1 ratio. A daughter cell that receives three chromosomes of a type will generally lose one, restoring the normal $2n$ chromosome number. Sometimes the resultant cell will contain one normal and one mutant allele, but

sometimes it will be homozygous for the mutant allele. Note that such aneuploidy (abnormal chromosome constitution) is generally damaging or lethal to relatively undifferentiated cells that have to develop into the many complex structures of an organism, but can often be tolerated in clones of cells that have limited fates and duties. (b) Mitotic recombination between a chromosome with a wild-type and a mutant allele, followed by chromosome segregation, can produce a cell that contains two copies of the mutant allele.

Some such mutations create oncogenes that turn on Hh target genes inappropriately; others are recessive mutations that affect negative regulators like Ptc1. As is the case for a number of other tumor-suppressor genes, complete loss of Ptc1 function would lead to early fetal death, since it is needed for development, so it is only the tumor cells that are homozygous *ptc1/ptc1*.

Many of the signaling pathways described in other chapters play roles in controlling embryonic development and cell proliferation in adult tissues. In recent years mutations affecting components of most of these signaling pathways have been linked to cancer (Figure 25-15). Indeed, once one gene in a developmental pathway has been linked to a type of human cancer, knowledge of the pathway gleaned from model organisms like worms, flies, or mice allows focused investigations of

the possible involvement of additional pathway genes in other cases of the cancer. For example, *APC*, the critical first gene mutated on the path to colon carcinoma, is now known to be part of the Wnt signaling pathway (see Chapter 16), which led to the discovery of the involvement of β -catenin mutations in colon cancer. Mutations in tumor-suppressor developmental genes promote tumor formation in tissues where the affected gene normally helps restrain growth. Thus the tumor-suppressor gene mutations will not cause cancers in tissues where the primary role of the developmental regulator is to control cell fate—what type of cell develops—but not cell division. Mutations in developmental proto-oncogenes may induce tumor formation in tissues where an affected gene normally promotes cell proliferation or in another tissue where the gene has become aberrantly active.

▲ **FIGURE 25-15 Cell circuitry that is affected by cancer-causing mutations.** Growth control and the cell cycle, the heart of cancer, are influenced by many types of signals, and the external inputs become integrated as the cell makes its decision about whether to divide or to continue dividing. Developmental pathways

give cells their identity, and along with that identity often comes a commitment to proliferate or not. Genes known to be mutated in cancer cells are shown in red. Less firmly established pathways are indicated with dashed lines. [From D. Hanahan and R. A. Weinberg, 2000, *Cell* 100:57.]

KEY CONCEPTS OF SECTION 25.2

The Genetic Basis of Cancer

- Dominant gain-of-function mutations in proto-oncogenes and recessive loss-of-function mutations in tumor-suppressor genes are oncogenic.
- Among the proteins encoded by proto-oncogenes are growth-promoting signaling proteins and their receptors, signal-transduction proteins, transcription factors, and apoptotic proteins (see Figure 25-11).
- An activating mutation of one of the two alleles of a proto-oncogene converts it to an oncogene. This can occur by point mutation, gene amplification, gene translocation, and overexpression.

- The first human oncogene to be identified encodes a constitutively active form of Ras, a signal-transduction protein. This oncogene was isolated from a human bladder carcinoma (see Figure 25-6).
- Slow-acting retroviruses can cause cancer by integrating near a proto-oncogene in such a way that transcription of the cellular gene is activated continuously and inappropriately.
- Tumor-suppressor genes encode proteins that directly or indirectly slow progression through the cell cycle, such as checkpoint-control proteins that arrest the cell cycle, components of growth-inhibiting signaling pathways, proapoptotic proteins, regulators of kinase activities, and DNA-repair enzymes.

- The first tumor-suppressor gene to be recognized, *RB*, is mutated in retinoblastoma and many other tumors; some component of the RB pathway is altered in most or all tumors.
- Inheritance of a single mutant allele of *RB* greatly increases the probability that a specific kind of cancer will develop, as is the case for many other tumor-suppressor genes (e.g., *APC* and *BRCA-1*).
- In individuals born heterozygous for a tumor-suppressor gene, a somatic cell can undergo loss of heterozygosity (LOH) by mitotic recombination, chromosome mis-segregation, mutation, gene silencing, or deletion (see Figure 25-14).
- Mutations in caretaker genes are genetically recessive, since having even one functional copy is usually sufficient to prevent serious DNA damage. However a single copy leaves the carrier subject to possible LOH.
- Many genes that regulate normal developmental processes encode proteins that function in various signaling pathways (see Figure 25-15). Their normal roles in regulating where and when growth occurs are reflected in the character of the tumors that arise when the genes are mutated.

25.3 Oncogenic Mutations in Growth-Promoting Proteins

Genes encoding each class of cell regulatory protein depicted in Figure 25-11 have been identified as proto-oncogenes or tumor-suppressor genes. In this section we examine in more detail how mutations that result in the unregulated, constitutive activity of certain proteins or in their overproduction promote cell proliferation and transformation, thereby contributing to carcinogenesis. In each case we see how a rare cell that has undergone a very particular sort of mutation becomes abundant owing to its uncontrolled proliferation.

Oncogenic Receptors Can Promote Proliferation in the Absence of External Growth Factors

Hyperactivation of a growth-inducing signaling protein, due to an alteration of the protein, might seem a likely mechanism of cancer, but in fact this rarely occurs. Only one such naturally occurring oncogene, *sis*, has been discovered. The *sis* oncogene, which encodes an altered form of platelet-derived growth factor (PDGF), can aberrantly stimulate proliferation of cells that normally express the PDGF receptor. A more common event is that cells begin to produce an unaltered growth factor that acts upon the cell that produces it. This is called **autocrine stimulation**.

In contrast, oncogenes encoding cell-surface receptors that transduce growth-promoting signals have been associated with several types of cancer. The receptors for many such growth factors have intrinsic protein-tyrosine kinase activity in their cytosolic domains, an activity that is quiescent until activated. Ligand binding to the external domains

of these **receptor tyrosine kinases (RTKs)** leads to their dimerization and activation of their kinase activity, initiating an intracellular signaling pathway that ultimately promotes proliferation.

In some cases, a point mutation changes a normal RTK into one that dimerizes and is constitutively active in the absence of ligand. For instance, a single point mutation converts the normal human EGF receptor 2 (Her2) receptor into the Neu oncoprotein (“neu” for its first known role, in neuroblastoma), which is an initiator of certain mouse cancers (Figure 25-16, left). Similarly, human tumors called *multiple endocrine neoplasia type 2* produce a constitutively active dimeric glia-derived neurotrophic factor (GDNF) receptor that results from a point mutation in the extracellular domain. GDNF receptor is a protein-tyrosine kinase, so the constitutively active form excessively phosphorylates its downstream target proteins. In other cases, deletion of much of the extracellular ligand-binding domain produces a constitutively active oncogenic receptor. For example, deletion of the

▲ **FIGURE 25-16** Effects of oncogenic mutations in proto-oncogenes that encode cell-surface receptors. *Left:* A mutation that alters a single amino acid (valine to glutamine) in the transmembrane region of the Her2 receptor causes dimerization of the receptor, even in the absence of the normal EGF-related ligand, making the oncoprotein Neu a constitutively active kinase. *Right:* A deletion that causes loss of the extracellular ligand-binding domain in the EGF receptor leads, for unknown reasons, to constitutive activation of the kinase activity of the resulting oncoprotein ErbB.

▲ **FIGURE 25-17 Domain structures of normal tropomyosin, the normal Trk receptor, and chimeric Trk oncoprotein.** A chromosomal translocation results in replacement of most of the extracellular domain of the normal human Trk protein, a receptor tyrosine kinase, with the N-terminal domain of nonmuscle

tropomyosin. Dimerized by the tropomyosin segment, the Trk oncoprotein kinase is constitutively active. Unlike the normal Trk, which is localized to the plasma membrane, the Trk oncoprotein is found in the cytosol. [See F. Coulier et al., 1989, *Mol. Cell Biol.* 9:15.]

extracellular domain of the normal EGF receptor (Figure 25-16, right) converts it to the dimeric ErbB oncoprotein (from erythroblastosis virus, where a viral version of the altered gene was first identified).

Mutations leading to overproduction of a normal RTK also can be oncogenic. For instance, many human breast cancers overproduce a normal Her2 receptor. As a result, the cells are stimulated to proliferate in the presence of very low concentrations of EGF and related hormones, concentrations too low to stimulate proliferation of normal cells (see Chapter 16).

Another mechanism for generating an oncogenic receptor is illustrated by the human *trk* oncogene, which was isolated from a colon carcinoma. This oncogene encodes a chimeric protein as the result of a chromosomal translocation that replaced the sequences encoding most of the extracellular domain of the normal Trk receptor with the sequences encoding the N-terminal amino acids of nonmuscle tropomyosin (Figure 25-17). The translocated tropomyosin segment can mediate dimerization of the chimeric Trk receptor by forming a coiled-coil structure, leading to activation of the kinase domains in the absence of ligand. The normal Trk protein is a cell-surface receptor tyrosine kinase that binds a nerve growth factor (Chapter 21). In contrast, the constitutively active Trk oncoprotein is localized in the cytosol, since the N-terminal signal sequence directing it to the membrane has been deleted.

Viral Activators of Growth-Factor Receptors Act as Oncoproteins

Viruses use their own tricks to cause cancer, presumably to increase the production of virus from infected cancer cells. For example, a retrovirus called *spleen focus-forming virus (SFFV)* induces erythroleukemia (a tumor of erythroid progenitors) in adult mice by manipulating a normal develop-

mental signal. The proliferation, survival, and differentiation of erythroid progenitors into mature red cells absolutely require erythropoietin (Epo) and the corresponding Epo receptor (see Figure 16-6). A mutant SFFV envelope glycoprotein, termed *gp55*, is responsible for the oncogenic effect of the virus. Although *gp55* cannot function as a normal retrovirus envelope protein in virus budding and infection, it has acquired the remarkable ability to bind to and activate Epo receptors in the same cell (Figure 25-18). By inappropriately and continuously stimulating the proliferation of

▲ **FIGURE 25-18 Activation of the erythropoietin (Epo) receptor by the natural ligand, Epo, or a viral oncoprotein.** Binding of Epo dimerizes the receptor and induces formation of erythrocytes from erythroid progenitor cells. Normally cancers occur when progenitor cells infected by the spleen focus-forming virus produce the Epo receptor and viral *gp55*, both localized to the plasma membrane. The transmembrane domains of dimeric *gp55* specifically bind the Epo receptor, dimerizing and activating the receptor in the absence of Epo. [See S. N. Constantinescu et al., 1999, *EMBO J.* 18:3334.]

erythroid progenitors, gp55 induces formation of excessive numbers of erythrocytes. Malignant clones of erythroid progenitors emerge several weeks after SFFV infection as a result of further mutations in these aberrantly proliferating cells.

Another example of this phenomenon is provided by human papillomavirus (HPV), the sexually transmitted DNA virus that causes cervical cancer and genital warts. A papillomavirus protein designated E5, which contains only 44 amino acids, spans the plasma membrane and forms a dimer or trimer. Each E5 polypeptide can form a stable complex with one endogenous receptor for PDGF, thereby aggregating two or more PDGF receptors within the plane of the plasma membrane. This mimics hormone-mediated receptor dimerization, causing sustained receptor activation and eventually cell transformation. As we will see later, the HPV genome also codes for several other proteins that act to inhibit tumor-suppressor genes, further contributing to cell transformation. Recently a vaccine against an HPV capsid protein (L1) has been found to protect against cervical cancer caused by at least some types of virus.

Many Oncogenes Encode Constitutively Active Signal-Transduction Proteins

A large number of oncogenes are derived from proto-oncogenes whose encoded proteins aid in transducing signals from an activated receptor to a cellular target. We describe several examples of such oncogenes; each is expressed in many types of tumor cells.

Ras Pathway Components Among the best-studied oncogenes in this category are the *ras^D* genes, which were the first nonviral oncogenes to be recognized. Any one of a number of changes in Ras protein can lead to its uncontrolled and therefore dominant activity. In particular, if a point mutation substitutes any amino acid for glycine at position 12 in the Ras sequence, the normal protein is converted into a constitutively active oncoprotein. This simple mutation reduces the protein's GTPase activity, thus maintaining Ras in the active GTP-bound state. Constitutively active Ras oncoproteins are produced by many types of human tumors, including bladder, colon, mammary, skin, and lung carcinomas, neuroblastomas, and leukemias.

As we saw in Chapter 16, Ras is a key component in transducing signals from activated receptors to a cascade of protein kinases. In the first part of this pathway, a signal from an activated RTK is carried via two adapter proteins to Ras, converting it to the active GTP-bound form (see Figure 16-20). In the second part of the pathway, activated Ras transmits the signal via two intermediate protein kinases to MAP kinase. The activated MAP kinase then phosphorylates a number of transcription factors that induce synthesis of important cell-cycle and differentiation-specific proteins (see Figure 16-25). Activating Ras mutations short-circuit the first part of this pathway, making upstream activation triggered by ligand binding to the receptor unnecessary. Oncogenes encoding other altered

components of the RTK/Ras/MAP kinase pathway also have been identified.

Constitutive Ras activation can also arise from a recessive loss-of-function mutation in a GTPase-accelerating protein (GAP). The normal GAP function is to accelerate hydrolysis of GTP and the conversion of active GTP-bound Ras to inactive GDP-bound Ras (see Figure 3-32). The loss of GAP leads to sustained Ras activation of downstream signal-transduction proteins. For example, neurofibromatosis, a benign tumor of the sheath cells that surround nerves, is caused by loss of both alleles of *NF1*, which encodes a Ras GAP-type protein. Individuals with neurofibromatosis have inherited a single mutant *NF1* allele; subsequent somatic mutation in the other allele leads to formation of neurofibromas. Thus *NF1*, like *RB*, is a tumor-suppressor gene, and neurofibromatosis, like hereditary retinoblastoma, is inherited as an autosomal dominant trait.

Src Protein Kinase Several oncogenes encode cytosolic protein kinases that normally transduce signals in a variety of intracellular signaling pathways. Indeed the first oncogene to be discovered, *v-src* from Rous sarcoma retrovirus, encodes a constitutively active protein-tyrosine kinase. At least eight mammalian proto-oncogenes encode a family of nonreceptor tyrosine kinases related to the *v-Src* protein. In addition to a catalytic domain, these kinases contain SH2 and SH3 protein-protein interaction domains. The kinase activity of cellular Src and related proteins normally is inactivated by phosphorylation of the tyrosine residue at position 527, which is six residues from the C-terminus (Figure 25-19a, b). Hydrolysis of phosphotyrosine 527 by a specific phosphatase enzyme normally activates c-Src. Tyrosine 527 is often missing or altered in Src oncoproteins that have constitutive kinase activity; that is, they do not require activation by a phosphatase (Figure 25-19b).

Abl Protein Kinase One oncogene encoding a cytosolic nonreceptor protein kinase is generated by a chromosome translocation that fuses a part of the *c-abl* gene, which encodes a tyrosine kinase, with part of the *bcr* gene, whose function is unknown (Figure 25-20a). One consequence of the fusion is that a hybrid protein is produced, and it has odd and dangerous properties. The normal c-Abl protein promotes branching of filamentous actin and extension of cell processes, so it may function primarily to control the cytoskeleton and cell shape. The chimeric oncoproteins encoded by the *bcr-abl* oncogene form a tetramer that exhibits unregulated and continuous Abl kinase activity (Figure 25-20b). (This is similar to dimerization and activation of the chimeric Trk oncoprotein shown in Figure 25-17.) Bcr-Abl can phosphorylate and thereby activate many intracellular signal-transduction proteins, and at least some of these proteins are not normal substrates of Abl. For instance, Bcr-Abl can activate JAK2 kinase and STAT5 transcription factor, which normally are activated by binding of growth factors (e.g., erythropoietin) to cell-surface receptors (see Figure 16-12). Bcr-Abl can also provide a docking site for

▲ FIGURE 25-19 Structure of Src tyrosine kinases and activation by an oncogenic mutation. (a) Three-dimensional structure of Hck, one of several Src kinases in mammals. Binding of phosphotyrosine 527 (P-Tyr 527) to the SH2 domain induces conformational strains in the SH3 and kinase domains, distorting the kinase active site so it is catalytically inactive. The kinase activity of cellular Src proteins is normally activated by removing the phosphate on tyrosine 527. (b) Domain structure of c-Src and v-Src. Phosphorylation of tyrosine 527 by Csk, another cellular tyrosine kinase, inactivates the Src kinase activity. The transforming v-Src oncoprotein encoded by Rous sarcoma virus is missing the C-terminal 18 amino acids including tyrosine 527 and thus is constitutively active. [Part (a) from F. Sicheri et al., 1997, *Nature* **385**:602; see also T. Pawson, 1997, *Nature* **385**:582, and W. Xu et al., 1997, *Nature* **385**:595.]

signal-transduction proteins through the Bcr part, thus potentially stimulating signal transduction.

The chromosomal translocation that forms *bcr-abl* generates the diagnostic *Philadelphia chromosome*, discovered in 1960 (see Figure 25-20a). If this translocation occurs in a hematopoietic cell in the bone marrow, the activity of the chimeric *bcr-abl* oncogene results in the initial phase of human chronic myelogenous leukemia (CML), characterized by an expansion in the number of white blood cells. A second loss-of-function mutation in a cell carrying *bcr-abl* (e.g., in *p53* or *RB*) leads to acute leukemia, which often kills the patient. The CML chromosome translocation was only the first of a long series of distinctive, or “signature,” chromo-

some translocations linked to particular forms of leukemia (Figure 25-21). Many of the gene fusions involve genes encoding transcriptional regulators, in particular, transcriptional regulators of Hox genes (Chapter 22). Each case presents an opportunity for greater understanding of the disease, earlier diagnosis, and new therapies. In the case of CML, that second step to successful therapy has already been taken.

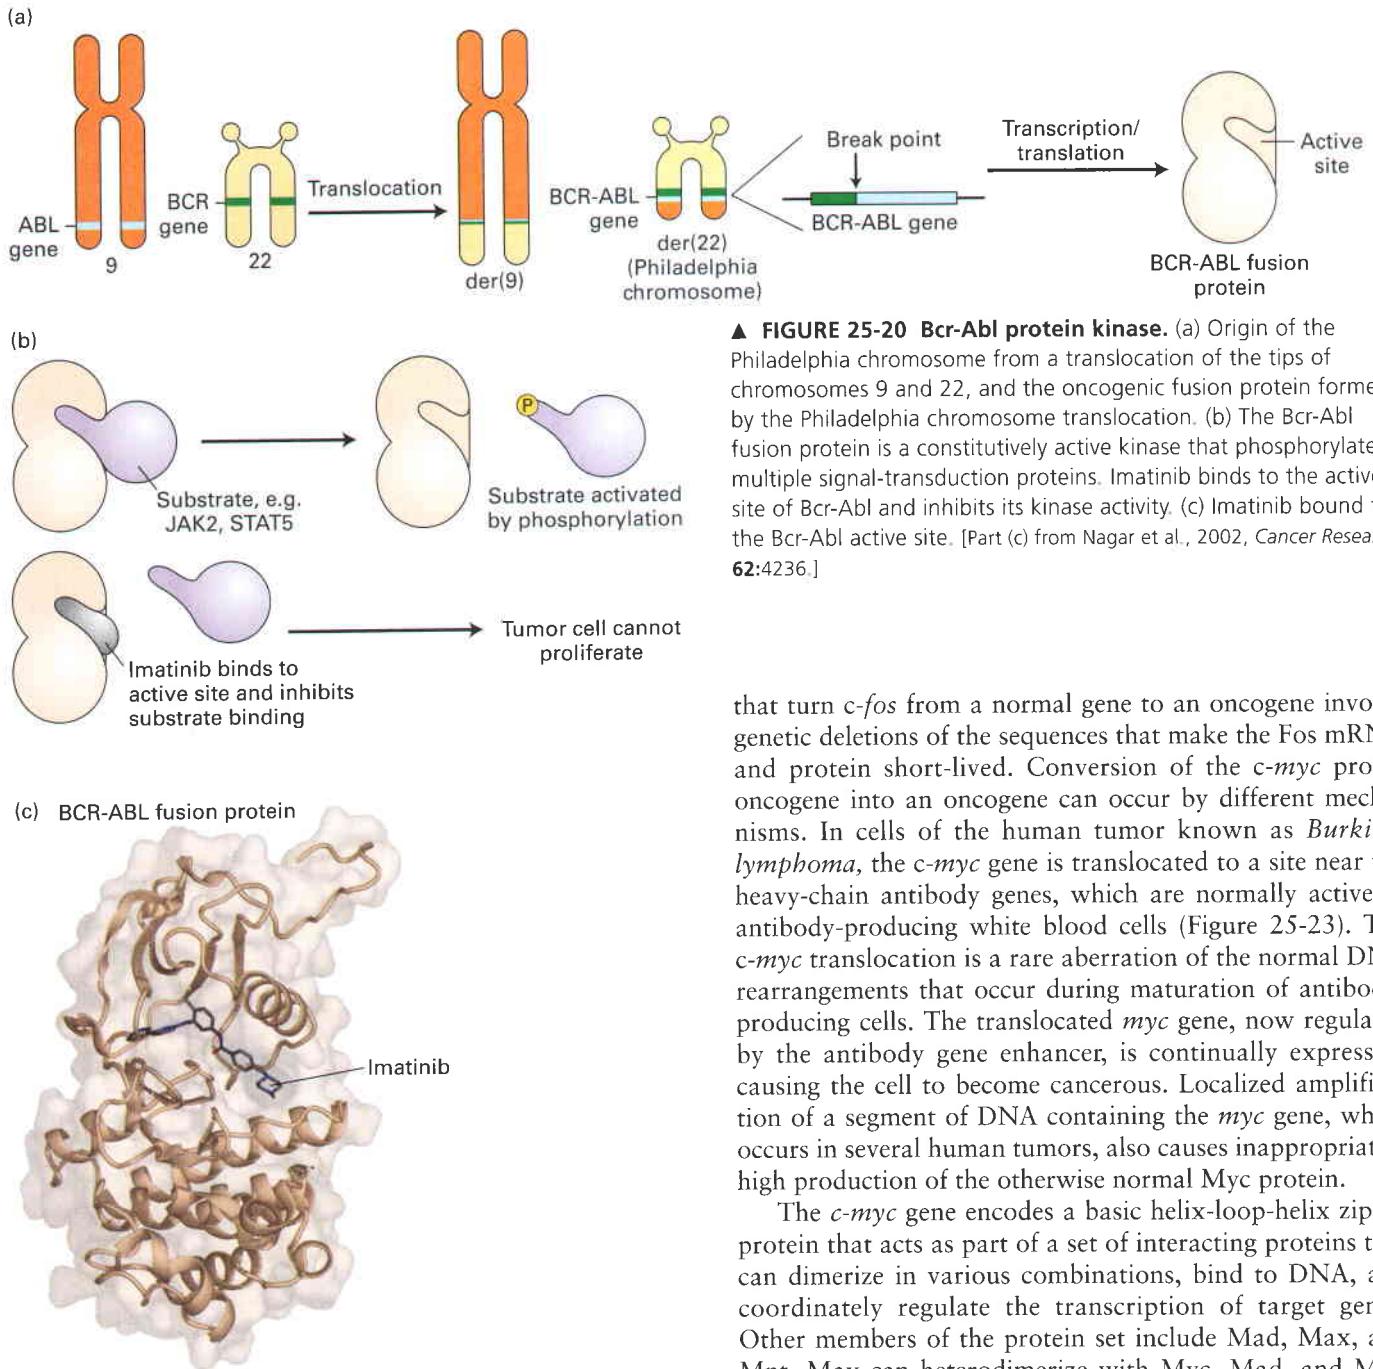

📖 After a painstaking search, an inhibitor of Abl kinase named imatinib (Gleevec) was identified as a possible treatment for CML in the early 1990s. Imatinib, which binds directly to the Abl kinase active site and inhibits kinase activity, is highly lethal to CML cells while sparing normal cells (see Figure 25-20c). After clinical trials showing imatinib is remarkably effective in treating CML despite some side effects, it was approved by the FDA in 2001, the first cancer drug targeted to a signal-transduction protein unique to tumor cells. Imatinib inhibits several other tyrosine kinases that are implicated in different cancers and has been successful in trials for treating these diseases, including forms of gastrointestinal tumors, as well. There are 96 tyrosine kinases encoded in the human genome, so drugs related to imatinib may be useful in controlling the activities of all these proteins. One ongoing challenge is that tumor cells can evolve to be resistant to imatinib and other such drugs, necessitating the invention of alternative drugs. ■

Inappropriate Production of Nuclear Transcription Factors Can Induce Transformation

Oncogenic mutations that create oncogenes or damage tumor-suppressor genes eventually cause changes in gene expression. Experimentally this can be measured by comparing the amounts of different mRNAs produced in normal versus tumor cells. As discussed earlier, we can now measure such differences in the expression of thousands of genes with DNA microarrays (see Figure 25-10).

Since the most direct effect on gene expression is exerted by transcription factors, it is not surprising that many oncogenes encode transcription factors. Two examples are *jun* and *fos*, which initially were identified in transforming retroviruses and later found to be overexpressed in some human tumors. The *c-jun* and *c-fos* proto-oncogenes encode proteins that sometimes associate to form a heterodimeric transcription factor, called *AP1*, that binds to a sequence found in promoters and enhancers of many genes (see Figure 7-29 and Chapter 16). Both Fos and Jun also can act independently as transcription factors. They function as oncoproteins by activating transcription of key genes that encode growth-promoting proteins or by inhibiting transcription of growth-repressing genes.

Many nuclear proto-oncogene proteins are produced when normal cells are stimulated to grow, indicating their direct role in growth control. For example, PDGF treatment of quiescent 3T3 cells induces an ≈ 50 -fold increase in the production of c-Fos and c-Myc, the normal products of the

▲ FIGURE 25-20 Bcr-Abl protein kinase. (a) Origin of the Philadelphia chromosome from a translocation of the tips of chromosomes 9 and 22, and the oncogenic fusion protein formed by the Philadelphia chromosome translocation. (b) The Bcr-Abl fusion protein is a constitutively active kinase that phosphorylates multiple signal-transduction proteins. Imatinib binds to the active site of Bcr-Abl and inhibits its kinase activity. (c) Imatinib bound to the Bcr-Abl active site. [Part (c) from Nagar et al., 2002, *Cancer Research* 62:4236.]

that turn *c-fos* from a normal gene to an oncogene involve genetic deletions of the sequences that make the Fos mRNA and protein short-lived. Conversion of the *c-myc* proto-oncogene into an oncogene can occur by different mechanisms. In cells of the human tumor known as *Burkitt's lymphoma*, the *c-myc* gene is translocated to a site near the heavy-chain antibody genes, which are normally active in antibody-producing white blood cells (Figure 25-23). The *c-myc* translocation is a rare aberration of the normal DNA rearrangements that occur during maturation of antibody-producing cells. The translocated *myc* gene, now regulated by the antibody gene enhancer, is continually expressed, causing the cell to become cancerous. Localized amplification of a segment of DNA containing the *myc* gene, which occurs in several human tumors, also causes inappropriately high production of the otherwise normal Myc protein.

The *c-myc* gene encodes a basic helix-loop-helix zipper protein that acts as part of a set of interacting proteins that can dimerize in various combinations, bind to DNA, and coordinately regulate the transcription of target genes. Other members of the protein set include Mad, Max, and Mnt. Max can heterodimerize with Myc, Mad, and Mnt. Myc-Max dimers regulate genes that control proliferation, such as cyclins. Mad proteins inhibit Myc proteins, which has led to an interest in using Mad proteins, or drugs that stimulate Mad proteins, to rein in excessive Myc activity that contributes to tumor formation. Myc protein complexes affect transcription by recruiting chromatin-modifying complexes containing histone acetyltransferases (which usually stimulate transcription, see Chapter 7) to Myc target genes. Mad and Mnt work with the Sin3 co-repressor protein to bring in histone deacetylases that help to block transcription. Together, all these proteins form a regulatory network that employs protein-protein association, variations in DNA binding, and transcriptional regulation to control cell proliferation.

fos and *myc* proto-oncogenes. Initially there is a transient rise of *c-Fos* and later a more prolonged rise of *c-Myc* (Figure 25-22). The levels of both proteins decline within a few hours, a regulatory effect that may, in normal cells, help to avoid cancer. As discussed in Chapter 20, *c-Fos* and *c-Myc* stimulate transcription of genes encoding proteins that promote progression through the G_1 phase of the cell cycle and the G_1 -to-S transition. In tumors, the oncogenic forms of these or other transcription factors are frequently expressed at high and unregulated levels.

In normal cells, *c-Fos* and *c-Myc* mRNAs and the proteins they encode are intrinsically unstable, leading to their rapid loss after the genes are induced. Some of the changes

▲ FIGURE 25-21 Chromosome translocations that form oncogenes and cause acute leukemias. With the exception of Bcr-Abl, the fusion proteins are transcription factors. ALL = acute lymphocytic leukemia; AML = acute myelocytic leukemia. The sizes of the wedges indicate the percentage of cases of the disease caused by different chromosome rearrangements. "Random" refers to chromosome breaks affecting as yet unknown genes, and "None" refers to cases where no chromosome rearrangement has been observed. Below each pie chart is a set of color codes indicating particular variants of the general class of leukemias. [From T. Look, 1997, *Science* 278:1059–1064.]

Molecular Cell Biology Is Changing How Cancer Is Treated

The imatinib story described earlier illustrates how genetics—the discovery of the Philadelphia chromosome and the critical oncogene it creates—together with biochemistry—discovery of the molecular action of the Abl protein—can lead to a powerful new therapy. In general, each difference between cancer cells and normal cells provides a new opportunity to identify

▲ EXPERIMENTAL FIGURE 25-22 Addition of serum to quiescent 3T3 cells yields a marked increase in the activity of two proto-oncogene products, c-Fos and c-Myc. Serum contains factors like platelet-derived growth factor (PDGF) that stimulate the growth of quiescent cells. One of the earliest effects of growth factors is to induce expression of *c-fos* and *c-myc*, whose encoded proteins are transcription factors. [See M. E. Greenberg and E. B. Ziff, 1984, *Nature* 311:433.]

a specific drug or treatment that kills just the cancer cells or at least stops their uncontrolled growth. Thus knowledge of the molecular cell biology of the tumors is critical information that can be exploited by researchers to develop anticancer treatments that more precisely target just cancer cells.

■ Breast cancer provides a good example of how molecular cell biology techniques have affected treatments, both curative and palliative. Until the rise in the incidence of lung cancer, resulting from an increase in women smokers, breast cancer was the most deadly cancer for women, and it remains the second most frequent cause of women's cancer deaths. The cause of breast cancer is unknown, but the frequency is increased if certain mutations are carried. Breast cancers are often diagnosed during routine mammogram (x-ray) examinations. Typically, a biopsy of a 1–2-cm tissue mass is taken to check the diagnosis, and is tested with antibodies to determine whether a high level of estrogen or prog-

▲ FIGURE 25-23 Chromosomal translocation in Burkitt's lymphoma. As a result of a translocation between chromosomes 8 and 14, the *c-myc* gene is placed adjacent to the gene for part of the antibody heavy chain (C_H), leading to overproduction of the Myc transcription factor in lymphocytes and hence their growth into a lymphoma.

estrogen receptor is present. These steroid receptors are capable of stimulating tumor growth, and are sometimes expressed at high levels in breast cancer cells. If either receptor is present, it is exploited in the treatment. A drug called tamoxifen, which inhibits the estrogen receptor, can be used to deprive the tumor cells of a growth-stimulating hormone. The biopsy is also tested for amplification of the proto-oncogene *HER2/NEU*, which as we have seen, encodes EGF receptor 2. A monoclonal antibody specific for Her2 has been a strikingly successful new treatment for the subset of breast cancers that overproduce Her2. Her2 antibody injected into the blood recognizes Her2 and causes it to be internalized, selectively killing the cancer cells without any apparent effect on normal breast (and other) cells that produce moderate amounts of Her2.

Breast cancer is treated with a combination of surgery, radiation therapy, and chemotherapy. The first step is surgical resection (removal) of the tumor and examination of lymph nodes for evidence of metastatic tumor, which is the major adverse prognostic factor. The subsequent treatment involves 6 weeks of radiation and 8 weeks of chemotherapy with three different types of agents. These harsh treatments are designed to kill the dividing cancer cells; however, they also cause a variety of side effects including suppression of blood cell production, hair loss, nausea, and neuropathy. This can reduce the strength of the immune system, risking infection, and cause weakness due to poor oxygen supply. To help, patients are given the growth factor G-CSF (Chapter 16) to promote neutrophil formation (a type of white blood cell that fights bacterial and fungal infections) and erythropoietin (Epo; Chapter 16) to stimulate red blood cell formation. Despite all this treatment, an average-risk woman (60 years old, 2-cm tumor, 1 positive lymph node) has a 30–40 percent 10-year risk of succumbing to her cancer. This risk can be reduced by 10–15 percent by hormone-blocking treatment such as tamoxifen, exploiting the molecular data that shows a hormone receptor present on the cancer cells. Mortality is reduced another 5–10 percent by treatment with antibodies against the Her2/Neu oncoprotein. Thus molecular biology is having a huge impact on breast cancer victim survival rates, though still far less than one would like. ■

The vision for the future of medicine is that the need for radiation and chemotherapy and perhaps even surgery will be substantially reduced, thus reducing toxicity and collateral damage. Increased knowledge of the molecular cell biology of cancer will allow drugs to be administered that are, first, more effective and harmless and, second, tuned to the particular properties of an individual's tumor cells. In breast tumor treatment we can already see progress in this direction.

KEY CONCEPTS OF SECTION 25.3

Oncogenic Mutations in Growth-Promoting Proteins

■ Mutations or chromosomal translocations that permit RTKs for growth factors to dimerize in the absence

of their normal ligands lead to constitutive receptor activity (see Figures 25-16 and 25-17). Such activation ultimately induces changes in gene expression that can transform cells. Overproduction of growth-factor receptors can have the same effect and lead to abnormal cell proliferation.

- Certain virus-encoded proteins can bind to and activate host-cell receptors for growth factors, thereby stimulating cell proliferation in the absence of normal signals.
- Most tumor cells produce constitutively active forms of one or more intracellular signal-transduction proteins, causing growth-promoting signaling in the absence of normal growth factors.
- A single point mutation in Ras, a key transducing protein in many signaling pathways that promote cell proliferation and differentiation, reduces its GTPase activity, thereby maintaining it in an activated state.
- The activity of Src, a cytosolic signal-transducing protein-tyrosine kinase, normally is regulated by reversible phosphorylation and dephosphorylation of a tyrosine residue near the C-terminus (see Figure 25-19). The unregulated activity of Src oncoproteins that lack this tyrosine promotes abnormal proliferation of many cells.
- The Philadelphia chromosome results from a chromosomal translocation that produces the chimeric *bcr-abl* oncogene. The unregulated Abl kinase activity of the Bcr-Abl oncoprotein is responsible for its oncogenic effect. An Abl kinase inhibitor (imatinib, or Gleevec) is effective in treating chronic myelogenous leukemia (CML) and may work against a few other cancers that are driven by related kinases (see Figure 25-20).
- Many other cases of leukemia are also due to chromosome rearrangements that create new fusion genes and fusion proteins. A rare chromosome breakage and rejoining event in a blood cell that creates the new protein causes uncontrolled growth. The cell grows into a clone of mutant cells.
- Inappropriate production of nuclear transcription factors such as Fos, Jun, and Myc can induce transformation. In Burkitt's lymphoma cells, *c-myc* is translocated close to an antibody gene, leading to overproduction of c-Myc (see Figure 25-23).
- Precise molecular analysis of early tumors is allowing the use of highly targeted drug treatments that are likely to be optimal for a particular case of a particular tumor. These refinements have allowed substantial reduction in breast cancer mortality. There are good prospects for still better targeting of treatments, based on continuing increases in the understanding of tumor-cell regulation.
- The advent of molecular techniques for characterizing individual tumors is allowing the application of drugs and antibody treatments that target the properties of a particular tumor. This permits more effective treatment of individual patients and reduces the use of drugs or antibodies that will be ineffective and possibly toxic.

Focus Animation: TGFβ Signaling Pathway

25.4 Mutations Causing Loss of Growth-Inhibiting and Cell-Cycle Controls

Normal growth and development depends on a finely tuned, highly regulated balance between growth-promoting and growth-inhibiting pathways. Mutations that disrupt this balance can lead to cancer. Most of the mutations discussed in the previous section cause inappropriate activity of growth-

promoting pathways. Just as critical are mutations that decrease the activity of growth-inhibiting pathways when they are needed.

For example, transforming growth factor β (TGFβ), despite its name, inhibits proliferation of many cell types, including most epithelial and immune system cells. Binding of TGFβ to its receptor induces activation of cytosolic Smad transcription factors (see Figure 16-4). After translocating to the nucleus Smads can promote expression of the gene encoding p15, an inhibitor of cyclin-dependent kinase 4 (CDK4), which causes cells to arrest in G₁. TGFβ signaling also promotes expression of genes encoding extracellular matrix proteins and plasminogen activator inhibitor 1 (PAI-1), which reduces the plasmin-catalyzed degradation of the matrix. Loss-of-function mutations in either TGFβ receptors or in Smads thus promote cell proliferation and probably contribute to the invasiveness and metastasis of tumor cells (Figure 25-24). Such mutations have in fact been found in a variety of human cancers. For example, deletion of the *Smad4* gene occurs in many human pancreatic cancers; retinoblastoma and colon cancer cells lack functional TGFβ receptors and therefore are unresponsive to TGFβ growth inhibition.

The complex mechanisms for regulating the eukaryotic cell cycle are prime targets for oncogenic mutations. Both positive- and negative-acting proteins precisely control the entry of cells into and their progression through the cell cycle, which consists of four main phases: G₁, S, G₂, and mitosis (see Figure 20-34). This regulatory system assures the proper coordination of cellular growth during G₁ and G₂, DNA synthesis during the S phase, and chromosome segregation and cell division during mitosis. In addition, cells that have sustained damage to their DNA normally are arrested before their DNA is replicated or in G₂ before chromosome segregation. This arrest allows time for the DNA damage to be repaired; alternatively, the arrested cells are directed either to commit suicide via programmed cell death, or at least not to divide. The whole cell-cycle control system functions to prevent cells from becoming cancerous. As might be expected, mutations in this system often lead to abnormal development or contribute to cancer.

Mutations That Promote Unregulated Passage from G₁ to S Phase Are Oncogenic

Once a cell progresses past a certain point in late G₁, called the **restriction point**, it becomes irreversibly committed to entering the S phase and replicating its DNA (see Figure 20-32). D-type cyclins, cyclin-dependent kinases (CDKs), and the Rb protein are all elements of the control system that regulate passage through the restriction point.

The expression of D-type cyclin genes is induced by many extracellular growth factors, or **mitogens**. These cyclins assemble with their partners CDK4 and CDK6 to generate catalytically active cyclin-CDK complexes, whose kinase activity promotes progression past the restriction point. Mitogen withdrawal prior to passage through the restriction point leads to accumulation of p16. Like p15 mentioned

above, p16 binds specifically to CDK4 and CDK6, thereby inhibiting their kinase activity and causing G₁ arrest. Under normal circumstances, phosphorylation of Rb protein is initiated midway through G₁ by active cyclin D–CDK4 and cyclin D–CDK6 complexes. Unphosphorylated Rb binds to and sequesters E2F transcription factors in the cytoplasm. E2F transcription factors stimulate transcription of genes encoding proteins required for DNA synthesis. Rb phosphorylation is completed by other cyclin-CDK complexes in late G₁, allowing release and activation of E2F transcription factors and G₁→S progression. The complete phosphorylation of Rb and its disassociation from E2F irreversibly commits the cell to DNA synthesis. Most tumors contain an oncogenic mutation that causes overproduction or loss of one of the components of this pathway such that the cells are propelled into the S phase in the absence of the proper extracellular growth signals (Figure 25-25; see also Figure 20-33).

Elevated levels of cyclin D1, one of the three D-type cyclins, for example, are found in many human cancers. In certain tumors of antibody-producing B lymphocytes, for instance, the *cyclin D1* gene is translocated such that its transcription is under control of an antibody-gene enhancer, causing elevated cyclin D1 production throughout the cell cycle, irrespective of extracellular signals. (This phenomenon is analogous to the *c-myc* translocation in Burkitt's lymphoma cells discussed earlier.) That cyclin D1 can function as an oncoprotein was shown by studies with transgenic mice in which the *cyclin D1* gene was placed under control of an enhancer specific for mammary ductal cells. Initially the ductal cells underwent hyperproliferation, and eventually breast tumors developed in these transgenic mice. Amplification of the *cyclin D1* gene and concomitant overproduction of the cyclin D1 protein is common in human breast cancer; the extra cyclin D1 helps to drive cells through the cell cycle.

▲ **FIGURE 25-25 Restriction point control.** Unphosphorylated Rb protein binds transcription factors collectively called E2F and thereby prevents E2F-mediated transcriptional activation of many genes whose products are required for DNA synthesis (e.g., DNA polymerase). The kinase activity of cyclin D–CDK4 phosphorylates Rb, thereby activating E2F; this kinase activity is inhibited by p16. Overproduction of cyclin D, a positive regulator, or loss of the negative regulators p16 and Rb commonly occurs in human cancers.

The proteins that function as cyclin-CDK inhibitors play an important role in regulating the cell cycle (Chapter 20). In particular, loss-of-function mutations that prevent p16 from inhibiting cyclin D–CDK4/6 kinase activity are common in several human cancers. As Figure 25-25 makes clear, loss of p16 mimics overproduction of cyclin D1, leading to Rb hyperphosphorylation and release of active E2F transcription factor. Thus p16 normally acts as a tumor suppressor. Although the *p16* tumor-suppressor gene is deleted in some human cancers, in others the *p16* sequence is normal. In some of these latter cancers (e.g., lung cancer) the *p16* gene, or genes encoding other functionally related proteins, is inactivated by hypermethylation of its promoter region, which prevents transcription. What promotes this change in the methylation of *p16* is not known, but it prevents production of this important cell-cycle control protein.

We've seen already that inactivating mutations in both *RB* alleles lead to childhood retinoblastoma, a relatively rare type of cancer. However, loss of *RB* gene function also is found in more common cancers that arise later in life (e.g., carcinomas of lung, breast, and bladder). These tissues, unlike retinal tissue, most likely produce other proteins (e.g., p107 and p130, both structurally related to p53) whose function is redundant with that of Rb, and thus loss of Rb is not so critical for preventing cancer. One way or another, Rb functions are eventually shut down. In addition to inactivating mutations, Rb function can be eliminated by the binding of an inhibitory protein, designated E7, that is encoded by human papillomavirus (HPV), another nasty viral trick to create virus-producing tissue. At present, this is known to occur only in cervical cancer.

Tumors with inactivating mutations in Rb generally produce normal levels of cyclin D1 and functional p16 protein. Conversely, tumor cells that overproduce cyclin D1 or have lost p16 function generally retain wild-type Rb. Thus loss of only one component of this regulatory system for controlling passage through the restriction point is all that is necessary to subvert normal growth control and set the stage for cancer.

Loss-of-Function Mutations Affecting Chromatin-Remodeling Proteins Contribute to Tumors

We have seen how mutations can undermine growth control by inactivating tumor-suppressor genes. However, these types of genes can also be silenced by repressive chromatin structures. In recent years the importance of *chromatin-remodeling complexes*, such as the SWI/SNF complex, in transcriptional control has become increasingly clear. These large and diverse multiprotein complexes have at their core an ATP-dependent helicase and often control histone modification and chromatin-remodeling (Chapter 7). By causing changes in the positions or structures of nucleosomes, SWI/SNF complexes make genes accessible or inaccessible to DNA-binding proteins that control transcription. If a gene is normally activated or repressed by SWI/SNF-mediated chromatin changes, mutations in the genes encoding the SWI or SNF proteins will cause changes in expression of the target gene.

Our knowledge of the target genes regulated by SWI/SNF and other such complexes is incomplete, but the targets evidently include some growth-regulating genes. For example, studies with transgenic mice suggest that SWI/SNF plays a role in repressing the *E2F* genes, thereby inhibiting progression through the cell cycle. The relationship between the genes that encode SWI/SNF proteins and the *E2F* gene was discovered in genetic experiments with flies. Transgenic flies were constructed to overexpress *E2F*, which resulted in mild growth defects. A search for mutations that increase the effect of the *E2F* overexpression in these flies identified three components of the SWI/SNF complex. That loss of function of these genes increases the proliferative effects of E2F indicates that SWI/SNF normally counteracts the function of the E2F transcription factor. Thus loss of SWI/SNF function, just like loss of Rb function, can lead to overgrowth and perhaps cancer. Indeed, in mice, Rb protein recruits SWI/SNF proteins to repress transcription of the *E2F* gene. Rb represses genes via this effect on E2F and by recruitment of histone deacetylases and histone methyltransferases.

Recent evidence from humans and mice has strongly implicated the *SNF5* gene in cancer. In humans, inactivating somatic *SNF5* mutations cause rhabdoid tumors, which most commonly form in the kidney, and an inherited (familial) disposition to form brain and other tumors. In mice, 15–30 percent of *snf5*⁻/*snf5*⁺ heterozygotes develop rhabdoid tumors, and in all cases the tumor cells have lost the remaining functional allele. Since nothing was known of the mechanism involved, microarray studies were used to discover regulatory changes in the tumors. These studies showed the gene-expression similarity of mouse and human tumors, and that the loss of *SNF5* leads to heightened expression of cell cycle genes including many regulated by E2F. Subsequent genetic experiments with double mutant *snf5*⁻/*snf5*⁻ *p53*⁻/*p53*⁻ mice showed synergism between the genes in tumor formation. In these mice the loss of *Snf5* will lead to derepression of the *E2F* gene, and the loss of p53 will cause the E2F to be fully active in promoting the G₁→S cell cycle transition.

With chromatin-remodeling complexes involved in so many aspects of transcriptional control, it is expected that SWI/SNF and similar complexes will be linked to many cancers. In humans, mutations in *Brg1*, which encodes the SWI/SNF catalytic subunit, have been found in prostate, lung, and breast tumors. Components of the SWI/SNF complex also have been found to associate with BRCA-1, the nuclear protein that helps suppress human breast cancer. BRCA-1 is involved in the repair of double-strand DNA breaks (as discussed in Chapter 4) and in transcriptional control, so the SWI/SNF complex may assist BRCA-1 in these functions.

Loss of p53 Abolishes the DNA-Damage Checkpoint

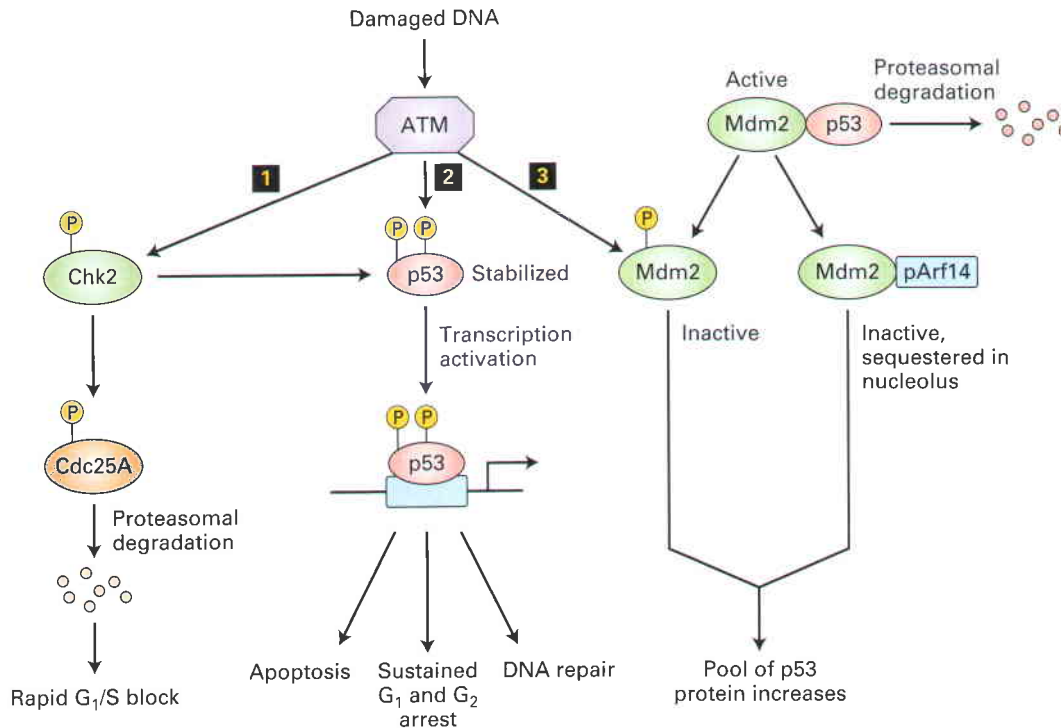

Cells with functional p53 become arrested in G₁ when exposed to DNA-damaging irradiation, whereas cells lacking

functional p53 do not. Unlike other cell-cycle proteins, p53 is present at very low levels in normal cells because it is extremely unstable and rapidly degraded. Mice lacking p53 are largely viable and healthy, except for a predisposition to develop multiple types of tumors. In normal mice the amount of p53 protein is heightened, a post-transcriptional response, only in stressful situations, such as ultraviolet or γ irradiation, heat, and low oxygen. DNA damage by γ irradiation or by other stresses somehow leads to the activation of ATM or ATR, serine kinases that phosphorylate and thereby stabilize p53, leading to a marked increase in its concentration (Figure 25-26). The stabilized p53 activates transcription of the gene encoding p21^{CIP}, which binds to and inhibits mammalian G₁ cyclin-CDK complexes, and a plethora of other genes. As a result, cells with damaged DNA are arrested in G₁, allowing time for DNA repair by mechanisms discussed in Chapter 4, or the cells permanently arrest, i.e., become senescent. In addition to its role in the G₁→S transition, p53-induced production of p21^{CIP} results in the inhibition of CDK1, which in turn blocks the cyclin B–CDK1 complex that is required for entry into mitosis, thus causing cells to arrest in G₂ (Figure 20-35, 4d). Directly or indirectly, p53 also represses expression of the genes encoding cyclin B and topoisomerase II, which also are required for the G₂→mitosis transition. Thus if DNA is damaged following its replication, p53-induced G₂ arrest will prevent its transmission to daughter cells.

As mentioned earlier, loss-of-function mutations in the *p53* gene occur in more than 50 percent of human cancers. When the p53 G₁ checkpoint control does not operate properly, damaged DNA can replicate, perpetuating mutations and DNA rearrangements that are passed on to daughter cells, contributing to the likelihood of transformation into metastatic cells. Interestingly, however, homozygous *p53*⁻/*p53*⁻ cells have no discernable defect in G₂ arrest, so there seem to be other ways to activate p21^{CIP} or different inhibitors of G₂ progression.

The active form of p53 is a tetramer of four identical subunits. A missense point mutation in one of the two *p53* alleles in a cell can abrogate almost all p53 activity because virtually all the oligomers will contain at least one defective subunit, and such oligomers have reduced ability to activate transcription. Oncogenic *p53* mutations thus act as **dominant negatives**, with mutations in a single allele causing a loss of function. The loss of function is incomplete, so in order to grow more rapidly, tumor cells still sometimes lose the remaining functional allele (loss of heterozygosity). As we learned in Chapter 5, dominant-negative mutations can occur in proteins whose active forms are multimeric or whose function depends on interactions with other proteins. In contrast, loss-of-function mutations in other tumor-suppressor genes (e.g., *RB*) are recessive because the encoded proteins function as monomers and mutation of a single allele has little functional consequence.

Under stressful conditions, the ATM kinase also phosphorylates and thus activates Chk2, a protein kinase that phosphorylates the protein phosphatase Cdc25A, marking it for ubiquitin-mediated destruction. This phosphatase normally removes the inhibitory phosphate from CDK2, a prerequisite

▲ **FIGURE 25-26 G₁ arrest in response to DNA damage.** The kinase activity of ATM is activated in response to DNA damage due to various stresses (e.g., UV irradiation, heat). Activated ATM then triggers three pathways leading to arrest in G₁: **1** Chk2 is phosphorylated and, in turn, phosphorylates Cdc25A, thereby marking it for degradation and blocking its role in CDK2 activation. **2** In a second pathway, phosphorylation of p53 stabilizes it, permitting p53-activated expression of genes encoding proteins that cause arrest in G₁ and in some cases G₂, promote apoptosis, or participate in DNA repair. **3** The

third pathway is another way of controlling the pool of p53. The Mdm2 protein in its active form can form a complex with p53, causing p53 ubiquitination and subsequent degradation by the proteasome. ATM phosphorylates Mdm2 to inactivate it, causing increased stabilization of p53. In addition, Mdm2 levels are controlled by pArf14 (pArf19 in mice), which binds Mdm2 and sequesters it in the nucleolus, where it cannot access p53. The human Mdm2 gene is frequently amplified in sarcomas, which presumably causes excessive inactivation of p53. See the text for a discussion.

for cells to enter the S phase. Decreased levels of Cdc25A thus block progression into and through the S phase (see Figure 25-26 and Figure 20-35, **4b**). Thus, loss-of-function mutations in the *ATM* or *Chk2* genes have some of the effects of *p53* mutations.

The activity of p53 normally is kept low by a protein called *Mdm2*. When Mdm2 is bound to p53, it inhibits the transcription-activating ability of p53 and catalyzes the addition of ubiquitin molecules, thus targeting p53 for proteasomal degradation. Phosphorylation of p53 by ATM or ATR displaces bound Mdm2 from p53, thereby stabilizing it. Because the *Mdm2* gene is itself transcriptionally activated by p53, Mdm2 functions in an autoregulatory feedback loop with p53, perhaps normally preventing excess p53 function. The *Mdm2* gene is amplified in many sarcomas and other human tumors that contain a normal *p53* gene. Even though functional p53 is produced by such tumor cells, the elevated Mdm2 levels reduce the p53 concentration enough to abolish the p53-induced G₁ arrest in response to irradiation.

The activity of p53 also is inhibited by a human papillomavirus (HPV) protein called *E6*. HPV encodes three proteins

that contribute to its ability to induce stable transformation and mitosis in a variety of cultured cells. Two of these—E6 and E7—bind to and inhibit the p53 and Rb tumor suppressors, respectively. Acting together, E6 and E7 are sufficient to induce transformation in the absence of mutations in cell regulatory proteins. Recall that the HPV E5 protein, which causes sustained activation of the PDGF receptor, enhances proliferation of the transformed cells.

The activity of p53 is not limited to inducing cell-cycle arrest. In addition, this multipurpose tumor suppressor stimulates production of pro-apoptotic proteins and DNA-repair enzymes (see Figure 25-26). Senescence and apoptosis may in fact be the most important means through which p53 prevents tumor growth.

Apoptotic Genes Can Function as Proto-oncogenes or Tumor-Suppressor Genes

During normal development many cells are designated for programmed cell death, also known as apoptosis (see Chapter 21). Many abnormalities, including errors in mitosis,

DNA damage, and an abnormal excess of cells not needed for development of a working organ, also can trigger apoptosis. In some cases, cell death appears to be the default situation, with signals required to ensure cell survival. Cells can receive instructions to live and instructions to die, and a complex regulatory system integrates the various kinds of information.

If cells do not die when they should and instead keep proliferating, a tumor may form. For example, chronic lymphoblastic leukemia (CLL) occurs because cells survive when they should be dying. The cells accumulate slowly, and most are not actively dividing, but they do not die. CLL cells have chromosomal translocations that activate a gene called *bcl-2*, which we now know to be a critical blocker of apoptosis (see Figure 21-37). The resultant inappropriate overproduction of Bcl-2 protein prevents normal apoptosis and allows survival of these tumor cells. CLL tumors are therefore attributable to a failure of cell death. Another dozen or so proto-oncogenes that are normally involved in negatively regulating apoptosis have been mutated to become oncogenes. Overproduction of their encoded proteins prevents apoptosis even when it is needed to stop cancer cells from growing.

Conversely, genes whose protein products stimulate apoptosis behave as tumor suppressors. An example is the *PTEN* gene discussed in Chapter 16. The phosphatase encoded by this gene dephosphorylates phosphatidylinositol 3,4,5-trisphosphate, a second messenger that functions in activation of protein kinase B (see Figure 16-30). Cells lacking *PTEN* phosphatase have elevated levels of phosphatidylinositol 3,4,5-trisphosphate and active protein kinase B, which promotes cell survival and prevents apoptosis by several pathways. Thus *PTEN* acts as a pro-apoptotic tumor suppressor by decreasing the anti-apoptotic effect of protein kinase B.

The most common pro-apoptotic tumor-suppressor gene implicated in human cancers is *p53*. Among the genes activated by *p53* are several encoding pro-apoptotic proteins such as Bax (see Figure 21-41). When most cells suffer extensive DNA damage or numerous other stresses such as growth-factor deprivation or hypoxia, the *p53*-induced expression of pro-apoptotic proteins leads to their quick demise (see Figure 25-26). While this may seem like a drastic response to DNA damage, it prevents proliferation of cells that are likely to accumulate multiple mutations. When *p53* function is lost, apoptosis cannot be induced and the accumulation of mutations required for cancer to develop becomes more likely.

Failure of Cell-Cycle Checkpoints Often Leads to Aneuploidy in Tumor Cells

It has long been known that chromosomal abnormalities abound in tumor cells. We have already encountered several examples of oncogenes that are formed by translocation, amplification, or both (e.g., *c-myc*, *bcr-abl*, *bcl-2*, and *cyclin D1*). Another chromosomal abnormality characteristic of nearly all tumor cells is **aneuploidy**, the pres-

ence of an aberrant number of chromosomes—generally too many.

Cells with abnormal numbers of chromosomes form when certain cell-cycle checkpoints are nonfunctional. As discussed in Chapter 20, the unreplicated-DNA checkpoint normally prevents entry into mitosis unless all chromosomes have completely replicated their DNA; the spindle-assembly checkpoint prevents entry into anaphase unless all the replicated chromosomes attach properly to the metaphase mitotic apparatus; and the chromosome-segregation checkpoint prevents exit from mitosis and cytokinesis if the chromosomes segregate improperly (see Figure 20-35, **1–3**). As advances are made in identifying the proteins that detect these abnormalities and mediate cell-cycle arrest, the molecular basis for the functional defects leading to aneuploidy in tumor cells will become clearer.

KEY CONCEPTS OF SECTION 25.4

Mutations Causing Loss of Growth-Inhibiting and Cell-Cycle Controls

- Loss of signaling by TGF β , a negative growth regulator, promotes cell proliferation and development of malignancy (see Figure 25-24).
- Overexpression of the proto-oncogene encoding cyclin D1 or loss of the tumor-suppressor genes encoding p16 and Rb can cause inappropriate, unregulated passage through the restriction point in late G₁. Such abnormalities are always seen in human tumors.
- Mutations affecting the SWI/SNF chromatin-remodeling complex, which participates in transcriptional control, are associated with a variety of tumors. In some cases, interaction of the SWI/SNF complex with a nuclear tumor-suppressor protein may have a repressing effect on gene expression.
- The p53 protein is a multifunctional tumor suppressor that promotes arrest in G₁ and G₂, apoptosis, and DNA repair in response to damaged DNA (see Figure 25-26).
- Loss-of-function mutations in the *p53* gene occur in more than 50 percent of human cancers. Overproduction of Mdm2, a protein that normally inhibits the activity of p53, occurs in several cancers (e.g., sarcomas) that express normal p53 protein. Thus in one way or another, the p53 stress-response pathway is inactivated to allow tumor growth.
- Human papillomavirus (HPV) encodes three oncogenic proteins: E6 (inhibits p53), E7 (inhibits Rb), and E5 (activates the PDGF receptor).
- Overproduction of anti-apoptotic proteins (e.g., Bcl-2) can lead to inappropriate cell survival and is associated with chronic lymphoblastic leukemia (CLL) and other cancers. Loss of proteins that promote apoptosis (e.g., p53 transcription factor and *PTEN* phosphatase) have a similar oncogenic effect.
- Genomic instability is a hallmark of cancer. Many types of DNA damage are observed in tumors. Most human tumor cells are aneuploid, containing an abnormal number

of chromosomes (usually too many). Failure of cell-cycle checkpoints that normally detect unreplicated DNA, improper spindle assembly, or mis-segregation of chromosomes permits aneuploid cells to arise.

25.5 Carcinogens and Caretaker Genes in Cancer

Carcinogens, which can be natural or produced by humans, are chemicals that cause cancer. Carcinogens cause mutations that reduce the function of tumor-suppressor genes, create oncogenes from proto-oncogenes, or damage DNA repair systems. As our previous discussion has shown, alterations in DNA that lead to malfunction of tumor-suppressor proteins and oncoproteins are the underlying cause of most cancers. These oncogenic mutations in key growth and cell-cycle regulatory genes include insertions, deletions, and base substitutions, as well as chromosomal amplifications and translocations. In addition, damage to caretaker genes comprising the DNA-repair systems (Chapter 4) leads to an increased mutation rate. Of the many mutations that accumulate, some affect cell-cycle regulators, and the cells bearing these may become cancerous. Furthermore, some DNA-repair mechanisms themselves are error-prone (see Figure 4-40). Those “repairs” also contribute to oncogenesis. The inability of tumor cells to maintain genomic integrity leads to formation of a heterogeneous population of malignant cells. For this reason, chemotherapy directed toward a single gene or even a group of genes is likely to be ineffective in wiping out all malignant cells. This problem adds to the interest in therapies that interfere with the blood supply to tumors or that in other ways act upon multiple types of tumor cells.

Stem cells (see Chapter 21), with their capability of carrying out many cell divisions, are a frequent source of cancer cells. Normal dividing cells usually employ several mechanisms to prevent accumulation of detrimental mutations that could lead to cancer. One form of protection against mutation for stem cells is their relatively low rate of division, which reduces the possibility of DNA damage incurred during DNA replication and mitosis. Furthermore, the progeny of stem cells do not have the ability to divide indefinitely. After several rounds of division they exit the cell cycle, reducing the possibility of mutation-induced misregulation of cell division associated with dangerous tumors. Also, if multiple mutations are required for a tumor to grow, attract a blood supply, invade neighboring tissues, and metastasize, a low rate of replication combined with the normal low rate of mutations (10^{-9}) provides further shielding from cancer. However, these safeguards can be overcome if a powerful mutagen reaches the cells, or if DNA repair is compromised and the mutation rate rises. When cells with stem cell-like growth properties are mutagenized by environmental poisons and unable to efficiently repair the damage, cancer can occur.

In this section, we explore the ways in which various carcinogens act on DNA to induce cancer, as well as how mutations in caretaker genes contribute to cancer by compromising the cell's ability to repair DNA damage. We end

the chapter with a discussion of a special enzyme called telomerase, another guardian of the genome that protects against DNA damage, and its role in cancer cells.

Carcinogens Induce Cancer by Damaging DNA

The ability of chemical and physical carcinogens to induce cancer is due to the DNA damage that they cause as well as the errors introduced into DNA during the cells' efforts to repair this damage. Thus carcinogens also are **mutagens**. The strongest evidence that carcinogens act as mutagens comes from the observation that cellular DNA altered by exposure of cells to carcinogens can change cultured cells, such as 3T3 cells, or cells implanted in mice into fast-growing cancer-like cells (see Figure 25-6). The mutagenic effect of carcinogens is roughly proportional to their ability to transform cells and induce cancer in animal models.

Although substances identified as chemical carcinogens have a broad range of structures with no obvious unifying features, they can be classified into two general categories. *Direct-acting carcinogens*, of which there are only a few, are mainly reactive electrophiles (compounds that seek out and react with electron-rich centers in other compounds). By chemically reacting with nitrogen and oxygen atoms in DNA, these compounds can modify bases in DNA so as to distort the normal pattern of base pairing. If these modified nucleotides are not repaired, they allow an incorrect nucleotide to be incorporated during replication. This type of carcinogen includes ethylmethane sulfonate (EMS), dimethyl sulfate (DMS), and nitrogen mustards.

In contrast, *indirect-acting carcinogens* generally are unreactive, often water-insoluble compounds that can act as potent cancer inducers only after the introduction of electrophilic centers. In animals, *cytochrome P-450 enzymes* are located in the endoplasmic reticulum of most cells and at especially high levels in liver cells. P-450 enzymes normally function to add electrophilic centers, such as OH groups, to nonpolar foreign chemicals, such as certain insecticides and therapeutic drugs, in order to solubilize them so that they can be excreted from the body. However, P-450 enzymes also can turn otherwise harmless chemicals into carcinogens. Indeed, most chemical carcinogens have little mutagenic effect until they have been modified by cellular enzymes.

Some Carcinogens Have Been Linked to Specific Cancers

In the earliest days of cancer awareness it became clear that at least some cancers are due to environmental poisons. For example in 1775 it was reported that the exposure of chimney sweeps to soot caused scrotal cancer, and in 1791 the use of snuff (tobacco) was reported to be associated with nasal cancer. Environmental chemicals were originally associated with cancer through experimental studies in animals. The classic experiment is to repeatedly paint a test substance on the back of a mouse and look for development of both local and systemic tumors in the animal. Such assays led to the purification of a pure chemical carcinogen from coal tar in 1933, benzo(a)pyrene. The role of radiation in

▲ **FIGURE 25-27 Chemical carcinogenesis by tobacco smoke.** Cigarette smoking provides a clear example of a deadly form of chemical carcinogenesis. The rates of lung cancer follow the rates of smoking, with about a 30-year lag. Women began to smoke in large numbers starting in the 1960s, and starting in the 1990s lung cancer passed breast cancer as the leading cause of women's cancer deaths. At the same time a gradual decrease in smoking rates among men starting in the 1960s has been reflected in a decrease in their lung cancer rate. [From the American Cancer Society.]

damaging chromosomes was first demonstrated in the 1920s using x-irradiated *Drosophila*. Later the ability of radiation to cause human cancer, especially leukemia, was dramatically shown by the increased rates of leukemia among survivors of the atomic bombs dropped in World

War II (ionizing radiation), and more recently by the increase in melanoma (skin cancer) in individuals exposed to too much sunlight (UV radiation).

Although chemical carcinogens are believed to be risk factors for many human cancers, a direct linkage to specific cancers has been established only in a few cases, the most important being lung cancer and the other cancers (laryngeal, pharynx, stomach, liver, pancreas, bladder, cervix, and more) that are associated with smoking. Epidemiological studies (Figure 25-27) first indicated that cigarette smoking was the major cause of lung cancer, but the reason was unclear until the discovery that about 60 percent of human lung cancers contain inactivating mutations in the *p53* gene. The chemical *benzo(a)pyrene*, found in cigarette smoke as well as coal tar, undergoes metabolic activation in the lung (Figure 25-28) to a potent mutagen that mainly causes conversion of guanine (G) to thymine (T) bases, a transversion mutation. When applied to cultured bronchial epithelial cells, activated *benzo(a)pyrene* induces many mutations, including inactivating mutations at codons 175, 248, and 273 of the *p53* gene. These same positions, all within the protein's DNA-binding domain, are major mutational hot spots in human lung cancer. In fact the nature of mutations in *p53* (and other cancer-related genes) gives clues as to the origin of the cancer. The G to T transversions caused by *benzo(a)pyrene*, for example, are present in the *p53* genes of about one-third of smokers' lung tumors. That type of mutation is relatively rare among the *p53* mutations found in

▲ **FIGURE 25-28 Enzymatic processing of benzo(a)pyrene to a more potent mutagen and carcinogen.** Liver enzymes, particularly P-450 enzymes, modify benzo(a)pyrene in a series of reactions, producing 7,8-diol-9,10-epoxide, a highly potent mutagenic species that reacts with DNA primarily at the N_2 atom of a guanine base in DNA. The resulting adduct, (+)-*trans-anti-B(a)P-N²-dG*, causes polymerase to insert an A rather than a C opposite the modified G

base. Next time the DNA is replicated, a T will be inserted opposite the A, and the mutation will be complete. Horizontal arrows indicate alterations toward greater potency, while vertical arrows indicate changes in the direction of reduced toxicity. The large 'O' symbol represents the rest of the multi-ring structure shown in the complete benzo(a)pyrene molecule at the left. [Adapted from E. L. Loechler, 2001, *Encyclopedia of Life Science*.]

other types of tumors. The carcinogen leaves its footprint. Thus, there is a strong correlation between one defined chemical carcinogen in cigarette smoke and human cancer. It is likely that other chemicals in cigarette smoke induce mutations in other genes, since it contains more than 60 carcinogens. Similarly, asbestos exposure is clearly linked to mesothelioma, a type of epithelial cancer.

Lung cancer is not the only major human cancer for which a clear-cut risk factor has been identified. *Aflatoxin*, a fungal metabolite found in moldy grains, induces liver cancer (Figure 25-29a). After chemical modification by liver enzymes, aflatoxin becomes linked to G residues in DNA and induces G-to-T transversions. Aflatoxin also causes a mutation in the *p53* gene. Furthermore, cooking meat at high temperatures causes chemical reactions that form *heterocyclic amines* (HCAs), which are potent mutagens and cause colon and breast carcinomas in animal models. HCAs react

with deoxyguanosine bases to form mutagenic adducts (Figure 25-29b). Exposure to other chemicals has been correlated with minor cancers. Hard evidence concerning dietary and environmental risk factors that would help us avoid other common cancers (e.g., breast, colon, and prostate cancer, leukemias) is generally lacking.

Loss of DNA-Repair Systems Can Lead to Cancer

Even without any external carcinogen or mutagen, normal processes generate a large amount of DNA damage. The damage is due to depurination reactions, to alkylation reactions, and to the generation of reactive species such as oxygen radicals, all of which alter DNA. It has been estimated that in every cell, more than 20,000 alterations to the DNA occur each day from just reactive oxygen species and depurination. Thus DNA repair is a crucial defense system.

◀ **FIGURE 25-29 Actions of two chemical carcinogens.** (a) Like all indirect-acting carcinogens, aflatoxin must undergo enzyme-catalyzed modification before it can react with DNA. In aflatoxin the colored double bond reacts with an oxygen atom, enabling it to react chemically with the N-7 atom of a guanine in DNA, forming a large bulky molecule that causes DNA polymerase to insert an A rather than a C opposite the modified G base during replication. This compound mutates the *p53* tumor-suppressor gene, causing G to T transversions, and is a known risk factor for human cancer. (b) Chemical reactions that occur in human food raised to high temperature, especially red meat, create about sixteen different types of heterocyclic amines (HCAs) from precursors such as creatine and amino acids. The HCA shown here, PhIP, is the most common one in the human diet. Cytochrome P-450 enzymes convert it to a very chemically reactive form, which reacts with a guanine base in DNA to form a DNA adduct that is mutagenic. PhIP causes breast and colon carcinomas in rodents and may be involved in human prostate cancer. Although the P-450 conversions occur mainly in liver cells, the HCAs can migrate to other tissues.

The normal role of caretaker genes is to prevent or repair DNA damage. Loss of the high-fidelity DNA-repair systems that are described in Chapter 4 correlates with increased risk for cancer. For example, humans who inherit mutations in genes that encode a crucial mismatch-repair or excision-repair protein have an enormously increased probability of developing certain cancers (Table 25-2). Without proper DNA repair, people with xeroderma pigmentosum (XP) or hereditary nonpolyposis colorectal cancer (HNPCC) have a propensity to accumulate mutations in many other genes, including those that are critical in controlling cell growth and proliferation. XP causes affected people to develop skin cancer at about a thousand times the normal rate. Seven of the eight known XP genes encode components of the excision-repair machinery, and in the absence of this repair mechanism, genes that control the cell cycle or otherwise regulate cell growth and death become mutated. HNPCC genes encode components of the mismatch-repair system, and

mutations in them account for a few percent of the cases of colon cancer. The cancers progress from benign polyps to full-fledged tumors much more rapidly than usual, presumably because the initial cancer cells are undergoing continuous mismatch mutagenesis without repair.

One gene frequently mutated in colon cancers because of the absence of mismatch repair encodes the type II receptor for TGF β (see Figure 25-24 and Chapter 16). The gene encoding this receptor contains a sequence of 10 adenines in a row. Because of “slippage” of DNA polymerase during replication, this sequence often undergoes mutation to a sequence containing 9 or 11 adenines. If the mutation is not fixed by the mismatch-repair system, the resultant frameshift in the protein-coding sequence abolishes production of the normal receptor protein. As noted earlier, such inactivating mutations make cells resistant to growth inhibition by TGF β , thereby contributing to the unregulated growth characteristic of these tumors. This

TABLE 25-2 Some Human Hereditary Diseases and Cancers Associated with DNA-Repair Defects

DISEASE	DNA-REPAIR SYSTEM AFFECTED	SENSITIVITY	CANCER SUSCEPTIBILITY	SYMPTOMS
PREVENTION OF POINT MUTATIONS, INSERTIONS, AND DELETIONS				
Hereditary nonpolyposis colorectal cancer	DNA mismatch repair	UV irradiation, chemical mutagens	Colon, ovary	Early development of tumors
Xeroderma pigmentosum	Nucleotide excision repair	UV irradiation, point mutations	Skin carcinomas, melanomas	Skin and eye photosensitivity, keratoses
REPAIR OF DOUBLE-STRAND BREAKS				
Bloom's syndrome	Repair of double-strand breaks by homologous recombination	Mild alkylating agents	Carcinomas, leukemias, lymphomas	Photosensitivity, facial telangiectases, chromosome alterations
Fanconi anemia	Repair of double-strand breaks by homologous recombination	DNA cross-linking agents, reactive oxidant chemicals	Acute myeloid leukemia, squamous-cell carcinomas	Developmental abnormalities including infertility and deformities of the skeleton; anemia
Hereditary breast cancer, BRCA-1 and BRCA-2 deficiency	Repair of double-strand breaks by homologous recombination		Breast and ovarian cancer	Breast and ovarian cancer

SOURCES: Modified from A. Kornberg and T. Baker, 1992, *DNA Replication*, 2d ed., W. H. Freeman and Company, p. 788; J. Hoeijmakers, 2001, *Nature* 411:366; and L. Thompson and D. Schild, 2002, *Mutation Res.* 509:49.

finding attests to the importance of mismatch repair in correcting genetic damage that might otherwise lead to uncontrolled cell proliferation.

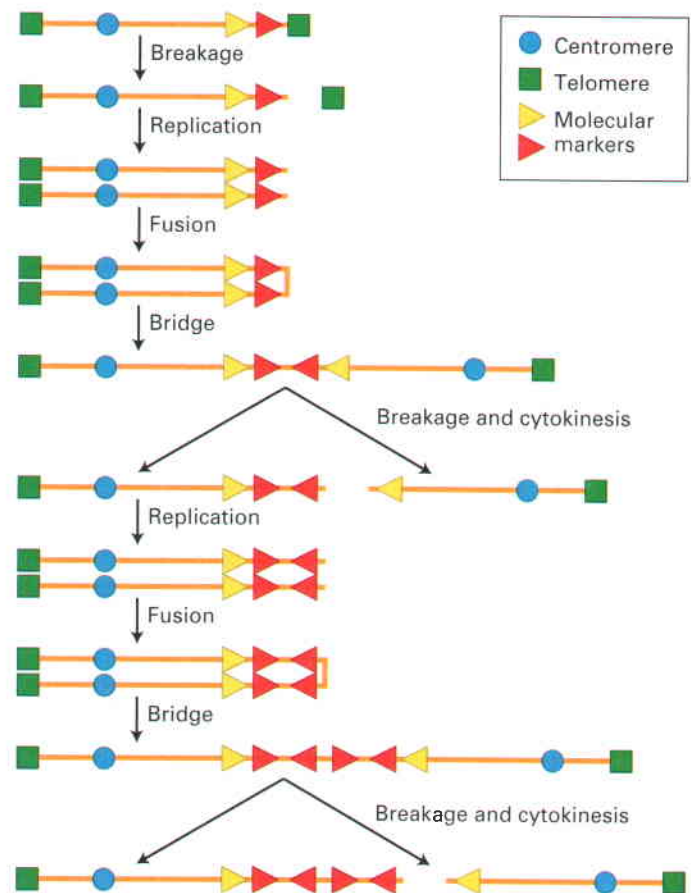

All DNA-repair mechanisms utilize a family of DNA polymerases to correct DNA damage. Nine of these polymerases, including one called *DNA polymerase β*, are capable of using templates that contain DNA adducts and other chemical modifications, even missing bases. These are called *lesion-bypass* DNA polymerases. Each member of the polymerase family has distinct capabilities to cope with particular types of DNA lesions. Presumably such polymerases are tolerated because often any repair is better than none. They are the polymerases of last resort, the ones used when more conventional and accurate polymerases are unable to perform, and they carry out a mutagenic replication process. DNA Pol β does not proofread and is overexpressed in certain tumors, perhaps because it is needed at high levels for cells to be able to divide at all in the face of a growing burden of mutations. Error-prone repair systems are thought to mediate much of, if not all, the carcinogenic effects of chemicals and radiation, since it is only after the repair that a heritable mutation exists. There is growing evidence that mutations in DNA Pol β are associated with tumors. When 189 tumors were examined, 58 had mutations in the DNA Pol β gene, and most of these mutations were found neither in normal tissue from the same patient nor in the normal spectrum of mutations found in different people. Expressing two of the mutant polymerase forms in mouse cells caused them to grow with a transformed appearance, with focus formation and anchorage independence.

Double-strand breaks are particularly severe lesions because incorrect rejoining of double strands of DNA can lead to gross chromosomal rearrangements and translocations such as those that produce a hybrid gene or bring a growth-regulatory gene under the control of a different promoter. Often the repair of such damage depends on using the homologous chromosome as a guide (Chapter 4). The B and T cells of the immune system are particularly susceptible to DNA rearrangements caused by double-strand breaks created during rearrangement of their immunoglobulin or T cell receptor genes, explaining the frequent involvement of these gene loci in leukemias and lymphomas. *BRCA-1* and *BRCA-2*, genes implicated in human breast and ovarian cancers, encode important components of DNA-break repair systems. Cells lacking one of the BRCA functions are unable to repair DNA where the homologous chromosome is providing the template for repair.

Telomerase Expression Contributes to Immortalization of Cancer Cells

Telomeres, the physical ends of linear chromosomes, consist of tandem arrays of a short DNA sequence, TTAGGG in vertebrates. Telomeres provide the solution to the end-replication problem—the inability of DNA polymerases to completely replicate the end of a double-stranded DNA molecule (Chapter 6). *Telomerase*, a reverse transcriptase that contains an RNA template, repeatedly adds TTAGGG

repeats to chromosome ends to lengthen or maintain the 3- to 20-kb regions of repeats that decorate the ends of human chromosomes (see Figure 6-49). Embryonic cells, germ-line cells, and stem cells produce telomerase, but most human somatic cells produce only a low level of telomerase as they enter S phase. As a result of having only modest telomerase function, their telomeres shorten with each cell cycle. Complete loss of telomeres leads to end-to-end chromosome fusions (Figure 25-30) and cell death. Extensive shortening of telomeres is recognized by the cell as a kind of DNA damage, with consequent stabilization and activation of p53 protein, leading to p53-triggered apoptosis.

▲ FIGURE 25-30 Chromosomal fusion and damage from loss of telomeres. The absence of a telomere from the end of a chromosome triggers a breakage-fusion-bridge (B-F-B) cycle, with consequent major damage to chromosome structures. The loss of a telomere, by breakage or due to the absence of telomerase, allows a chromatid to fuse with its sister chromatid during mitosis. A bridge is formed, and when the centromeres separate at anaphase, the two chromatids are joined together and must break. In each daughter cell, again chromosomes lack telomeres, so the cycle repeats. The sites of the breaks are usually within 1 megabase of the telomere, and each daughter cell will have either terminal deletions or an amplification of terminal genes. Telomeres are often lost even in cancer cells that have ample telomerase, so multiple mechanisms can trigger the B-F-B cycle. [Adapted from S. M. Bailey and J. P. Murnane, 2006, *Nucl. Acid Res.* **34**:2408.]

▲ FIGURE 25-31 Loss of telomeres normally limits the number of rounds of cell division. Replication of the ends of chromosomes, the telomeres, requires a special enzyme called *telomerase*. Telomerase carries with it a short RNA template, which is used to guide the assembly of repeats of TTAGGG on the ends of chromosomes. Human embryonic cells have 8–10 kb of these repeats on each chromosome end. Because DNA polymerase requires a primer and there is none at the end of the lagging strand, it cannot replicate DNA fully at the ends (see Chapter 6). Telomerase is therefore necessary, and in its absence chromosomes shrink during each mitosis. Telomerase is present in stem cells and germ-line cells, where it is needed to keep telomeres long and allow essentially indefinite rounds of cell division. In most somatic cells, telomerase is at low or very low levels, and the length of telomeres is consequently gradually eroded. The length of the telomeres therefore provides one limit to replicative capacity. Complete loss of telomere repeats leads to triggering of DNA repair and apoptosis. Cancer cells often produce telomerase, allowing them to divide indefinitely and evade programmed death.

Figure 25-31 summarizes the effects of different numbers of telomere repeats.

Most tumor cells, despite their rapid proliferation rate, overcome this fate by producing telomerase. Many researchers believe that telomerase expression is essential for a tumor cell to become immortal, and specific inhibitors of telomerase have been suggested as cancer therapeutic agents. Introduction of telomerase-producing transgenes into cultured human cells that otherwise lack the enzyme can extend their lifespan by more than 20 doublings while maintaining telomere length. Conversely, treating human tumor cells (HeLa cells) in culture with anti-sense RNA against telomerase caused them to cease growth in about four weeks. Dominant-negative telomerases, such as those carrying a modified RNA template, can interfere with cancer cell growth. For example, when

such a mutant (Figure 25-32) was expressed in prostate or breast cancer cells in culture, the cells became apoptotic. Furthermore, human breast tumor cells carrying the mutant telomerase, transplanted into a mouse, grew at lower rates.

 The prognosis for neuroblastoma, a pediatric tumor of the peripheral nervous system, can be ascertained by assessing the level of telomerase activity in tumor cells. High levels of telomerase predict a poor response to therapy, while low levels predict a good response. The level of *N-myc* protein, a transcription factor that regulates expression of telomerase, is also predictive for the outcomes of these tumors. Tumors that have amplified the *N-myc* gene to high copy number have a worse prognosis. These results show the practical importance of understanding the circuitry of telomere synthesis and its regulation. ■

Genetic approaches have further improved our understanding of the role of telomerase in cancer. The initial finding that mice homozygous for a deletion of the RNA subunit of telomerase are viable and fertile was surprising. However, after four to six generations defects began to appear in the telomerase-null mice as their very long telomeres (40–60 kb) became significantly shorter. The defects included depletion of tissues that require high rates of cell division, like skin and intestine, and infertility.

When treated with carcinogens, telomerase-null mice develop tumors less readily than normal mice do. For example, skin papillomas induced by a combination of chemical carcinogens occur 20 times less frequently in mice lacking a functional telomerase than in normal mice, presumably because p53-triggered apoptosis is induced in response to the ever shortening telomeres of cells that have begun to divide. However, if both telomerase and p53 are absent, there is an increased rate of epithelial tumors such as squamous-cell carcinoma, colon, and breast cancer. Mice with an *APC* mutation normally develop colon tumors, and these too are reduced if the mice lack telomerase. Some other tumors are less affected by loss of telomerase. These studies demonstrate the relevance of telomerase for unbridled cell division and make the enzyme a possible target for chemotherapy.

KEY CONCEPTS OF SECTION 25.5

Carcinogens and Caretaker Genes in Cancer

- Changes in the DNA sequence result from copying errors and the effects of various physical and chemical agents, or carcinogens. All carcinogens are mutagens; that is, they alter one or more nucleotides in DNA.
- Indirect-acting carcinogens, the most common type, must be activated before they can damage DNA. In animals, metabolic activation occurs via the cytochrome P-450 system, a pathway generally used by cells to rid themselves of

transcription. In the future, techniques for systematically measuring protein production, modification, and localization, all important measures of cell states, will give us even more refined portraits of cells. Tumors now viewed as identical or very similar will instead be recognized as distinctly different and given appropriately different treatments. Earlier detection of tumors, based on better monitoring of cell properties, should allow more successful treatment. A focus on that particularly destructive process, metastasis, should be successful in identifying more of the mechanisms used by cells to migrate, attach, and invade. Manipulation of angiogenesis continues to look hopeful as a means of suffocating tumors.

The molecular cell biology of cancer provides avenues for new therapies, but prevention remains crucial and preferable to therapy. Avoidance of obvious carcinogens, in particular cigarette smoke, can significantly reduce the incidence of lung cancer and perhaps other kinds, as well. Beyond minimizing exposure to carcinogens such as smoke or sunlight, certain specific approaches are now feasible. New knowledge of the involvement of human papillomavirus 16 in most cases of cervical cancer led to the development and Federal Drug Administration approval of a cancer vaccine that in tests prevented three-quarters of all cervical cancers. Antibodies against cell-surface markers that distinguish cancer cells are a source of great hope, especially after successes with the clinical use of monoclonal antibodies against human EGF receptor 2 (Her2), a protein involved in some cases of human breast cancer. Further steps must involve medicine and science. Understanding the cell biology of cancer is a critical first step toward prevention and cure, but the next steps are hard. The success with Gleevec (imatinib) against leukemia is exceptional; many cancers remain difficult to treat and cause enormous suffering. Since *cancer* is a term for a group of highly diverse diseases, interventions that are successful for one type may not be useful for others. Despite these daunting realities, we are beginning to reap the benefits of decades of research exploring the molecular biology of the cell. We hope that many of the readers of this book will help to overcome the obstacles that remain.

 transformation 1113

Review the Concepts

1. What characteristics distinguish benign from malignant tumors? With respect to gene mutations, what distinguishes benign colon polyps from malignant colon carcinoma?
2. Ninety percent of cancer deaths are caused by metastatic rather than primary tumors. Define *metastasis*. Explain the rationale for the following new cancer treatments: (a) batimastat, an inhibitor of matrix metalloproteinases and of the plasminogen activator receptor, (b) antibodies that block the function of integrins, integral membrane proteins that mediate attachment of cells to the basement membrane and extracellular matrices of various tissues, and (c) bisphosphonate, which inhibits the function of osteoclasts. Osteoclasts are cells that digest bones, for example, in remodeling during growth or healing. They can be recruited to a bone-digesting task by signals from other cells.
3. Because of oxygen and nutrient requirements, cells in a tissue must reside within 100 μ m of a blood vessel. Based on this information, explain why many malignant tumors often possess gain-of-function mutations in one of the following genes: *bFGF*, *TGF α* , and *VEGF*.
4. Ras oncogenes have been identified in human tumor cells using cell transformation assays with a line of cultured mouse fibroblasts called *3T3 cells*. How does the 3T3 cell transformation assay work? Why can transfection with a ras gene transform 3T3 cells but not normal cultured primary fibroblast cells?
5. What hypothesis explains the observations that incidence of human cancers increases exponentially with age? Give an example of data that confirms the hypothesis.
6. Distinguish between proto-oncogenes and tumor-suppressor genes. To become cancer-promoting, do proto-oncogenes and tumor-suppressor genes undergo gain-of-function or loss-of-function mutations? Classify the following genes as proto-oncogenes or tumor-suppressor genes: *p53*, *ras*, *Bcl-2*, *jun*, and *p16*.
7. Explain how DNA microarray analysis can distinguish between phenotypically similar lymphomas.
8. Hereditary retinoblastoma generally affects children in both eyes, while spontaneous retinoblastoma usually occurs during adulthood only in one eye. Explain the genetic basis for the epidemiological distinction between these two forms of retinoblastoma. Explain the apparent paradox: loss-of-function mutations in tumor-suppressor genes act recessively, yet hereditary retinoblastoma is inherited as an autosomal dominant.
9. Explain the concept of loss of heterozygosity (LOH). Why do most cancer cells exhibit LOH of one or more

genes? How does failure of the spindle-assembly checkpoint lead to loss of heterozygosity?

10. Many malignant tumors are characterized by the activation of one or more growth-factor receptors. What is the catalytic activity associated with transmembrane growth-factor receptors such as the EGF receptor? Describe how the following events lead to activation of the relevant growth-factor receptor: (a) expression of the viral protein gp55, (b) translocation that replaces the extracellular domain of the Trk receptor with the N-terminal region of tropomyosin, (c) point mutation that converts a valine to glutamine within the transmembrane region of the Her2 receptor.

11. Describe the common signal-transduction event that is perturbed by cancer-promoting mutations in the genes encoding Ras and NF-1. Why are mutations in Ras more commonly found in cancers than mutations in NF-1?

12. What is the structural distinction between the proteins encoded by *c-src* and *v-src*? How does this difference render *v-src* oncogenic?

13. Describe the mutational event that produces the *myc* oncogene in Burkitt's lymphoma. Why does the particular mechanism for generating oncogenic *myc* result in a lymphoma rather than another type of cancer? Describe another mechanism for generating oncogenic *myc*.

14. Pancreatic cancers often possess loss-of-function mutations in the gene that encodes the Smad4 protein. How does this mutation promote the loss of growth inhibition and highly metastatic phenotype of pancreatic tumors?

15. Several strains of human papilloma virus (HPV) can cause cervical cancer. These pathogenic strains produce three proteins that contribute to host-cell transformation. What are these three viral proteins? Describe how each interacts with its target host protein.

16. Loss of p53 function occurs in the majority of human tumors. Name two ways in which loss of p53 function contributes to a malignant phenotype. Explain how benzo(*a*)pyrene can cause loss of p53 function.

17. Which human cell types possess telomerase activity? What characteristic of cancer is promoted by expression of telomerase? What concerns does this pose for medical therapies involving stem cells?

Analyze the Data

Cigarette smoking is a major risk factor in the development of non-small cell lung cancer (NSCLC), which accounts for 80 percent of all lung cancers. NSCLC is characterized by poor prognosis and resistance to chemotherapy. To understand if nicotine affects this resistance, lung cancer cell lines were treated with the chemotherapeutic drugs gemcitabine, Cisplatin, and Taxol, in the presence and absence of nicotine (see Dasgupta et al., 2006, Proc. Nat'l Acad. Sci. USA 103:6332–6337).

a. Three different NSCLC cells lines, A549, NCI-H23, and H1299, were examined by the TUNEL assay, which de-

fects cells that are undergoing apoptosis (programmed cell death). The cells were either untreated or treated with one of the three chemotherapeutic drugs in the presence or absence of nicotine. The following data were obtained. Why are these chemotherapeutic drugs potentially useful for the treatment of lung cancer, and how does nicotine affect their potential usefulness?

b. A549 cells were incubated with the drugs as in part (a), and in an additional chemotherapeutic drug, camptothecin, in the presence or absence of nicotine. The cells were lysed, extracts were run on SDS gels, and then the gels were blotted and probed with antibodies against the indicated proteins. PARP is a protein that is cleaved during apoptosis. What can you deduce from these data about the effects of nicotine? What is the purpose of assessing the levels of p53, p21, and actin?

c. Survivin and XIAP are both members of the inhibitor of apoptosis (IAP) family, proteins that protect cells against apoptosis. A549 cells were treated with the chemotherapeutic drugs in the presence or absence of

nicotine and presence or absence of LY294002, an inhibitor of PI-3 kinase (see Chapter 16). The levels of PARP, XIAP, survivin, and actin were assessed, as shown in the Western blots below. The graph shows the results of a TUNEL assay in which A549 cells have been transfected with the indicated siRNAs. “None” indicates the amount of cell death with no transfected RNA. Control-siRNAs 1 and 2 are irrelevant RNAs added to control for nonspecific effects of having an interfering RNA entering the cells. What do these studies suggest about the mechanism of nicotine action?

d. Can you provide a biological explanation for why the prognosis is poorer for patients who smoke during chemotherapy compared with those who quit smoking prior to it?

Boldfaced terms within a definition are also defined in this glossary. Figures and tables that illustrate defined terms are noted in parentheses.

AAA ATPase family A group of proteins that couple hydrolysis of ATP with large molecular movements usually associated with unfolding of protein substrates or the disassembly of multisubunit protein complexes.

ABC superfamily A large group of integral membrane proteins that often function as ATP-powered **membrane transport proteins** to move diverse molecules (e.g., phospholipids, cholesterol, sugars, ions, peptides) across cellular membranes. (Figure 11-14)

acetylcholine (ACh) Neurotransmitter that functions at vertebrate neuromuscular junctions and at various neuron–neuron synapses in the brain and peripheral nervous system. (Figure 23-19)

acetyl CoA Small, water-soluble metabolite comprising an acetyl group linked to coenzyme A (CoA). The acetyl group is transferred to citrate in the **citric acid cycle** and is used as a carbon source in the synthesis of fatty acids, steroids, and other molecules. (Figure 12-9)

acid Any compound that can donate a proton (H^+). The carboxyl and phosphate groups are the primary acidic groups in biological macromolecules.

actin Abundant structural protein in eukaryotic cells that interacts with many other proteins. The monomeric globular form (*G-actin*) polymerizes to form actin filaments (*F-actin*). In muscle cells, F-actin interacts with **myosin** during contraction. See also **microfilament**. (Figure 17-5)

action potential Rapid, transient, all-or-none electrical activity propagated in the plasma membrane of excitable cells (e.g., neurons and muscle cells) as the result of the selective opening and closing of voltage-gated Na^+ and K^+ channels. (Figures 23-3 and 23-9)

activation energy The input of energy required to (overcome the barrier to) initiate a chemical reaction. By reducing the activation energy, an **enzyme** increases the rate of a reaction. (Figure 2-30)

activator Specific **transcription factor** that stimulates transcription.

active site Specific region of an enzyme that binds a **substrate** molecule(s) and promotes a chemical change in the bound substrate. (Figure 3-21)

active transport Protein-mediated movement of an ion or small molecule across a membrane against its concentration gradient or electrochemical gradient driven by the coupled hydrolysis of ATP. (Figure 11-3, [1]; Table 11-1)

adenosine triphosphate (ATP) See **ATP**.

adenylyl cyclase One of several enzymes that is activated by binding of certain ligands to their cell-surface receptors and catalyzes formation of cyclic AMP (cAMP) from ATP; also called *adenylate cyclase*. (Figures 15-21 and 15-22)

adhesion receptor Protein in the plasma membrane of animal cells that binds components of the **extracellular matrix**, thereby mediating cell–matrix adhesion. The **integrins** are major adhesion receptors. (Figure 19-1, [5])

aerobic Referring to a cell, organism, or metabolic process that utilizes gaseous oxygen (O_2) or that can grow in the presence of O_2 .

aerobic oxidation Oxygen-requiring metabolism of sugars and fatty acids to CO_2 and H_2O coupled to the synthesis of ATP.

agonist A molecule, often synthetic, that mimics the biological function of a natural molecule (e.g., a hormone).

allele One of two or more alternative forms of a gene. Diploid cells contain two alleles of each gene, located at the corresponding site (locus) on **homologous chromosomes**.

allosteric Referring to proteins and cellular processes that are regulated by **allostery**.

allostery Change in the tertiary and/or quaternary structure of a protein induced by binding of a small molecule to a specific regulatory site, causing a change in the protein's activity.

alpha (α) carbon atom (C_α) In amino acids, the central carbon atom that is bonded to four different chemical groups (except in glycine) including the **side chain**, or R group. (Figure 2-4)

alpha (α) helix Common protein **secondary structure** in which the linear sequence of amino acids is folded into a right-handed spiral stabilized by hydrogen bonds between carboxyl and amide groups in the backbone. (Figure 3-4)

alternative splicing Process by which the exons of one pre-mRNA are spliced together in different combinations, generating two or more different mature mRNAs from a single pre-mRNA. (Figure 4-16)

amino acid An organic compound containing at least one amino group and one carboxyl group. In the amino acids that are the **monomers** for building proteins, an amino group and carboxyl group are linked to a central carbon atom, the α carbon, to which a variable side chain is attached. (Figures 2-4 and 2-14)

aminoacyl-tRNA Activated form of an amino acid, used in protein synthesis, consisting of an amino acid linked via a high-energy ester bond to the 3'-hydroxyl group of a tRNA molecule. (Figure 4-19)

amphipathic Referring to a molecule or structure that has both a **hydrophobic** and a **hydrophilic** part.

anaerobic Referring to a cell, organism, or metabolic process that functions in the absence of gaseous oxygen (O_2).

anaphase Mitotic stage during which the sister **chromatids** (or duplicated homologues in meiosis I) separate and move apart (segregate) toward the spindle poles. (Figure 18-34)

anchoring junctions Specialized regions on the cell surface containing **cell-adhesion molecules** or **adhesion receptors**; include *adherens junctions* and *desmosomes*, which mediate cell–cell adhesion, and *hemidesmosomes*, which mediate cell–matrix adhesion. (Figures 19-12 and 19-14)

aneuploidy Any deviation from the normal **diploid** number of chromosomes in which extra copies of one or more chromosomes are present or one of the normal copies is missing.

anion A negatively charged ion.

antagonist A molecule, often synthetic, that blocks the biological function of a natural molecule (e.g., hormone).

antibody A protein (immunoglobulin), normally produced in response to an **antigen**, that interacts with a particular site (**epitope**) on the same antigen and facilitates its clearance from the body. (Figure 3-19)

anticodon Sequence of three nucleotides in a tRNA that is complementary to a **codon** in an mRNA. During protein synthesis, base pairing between a codon and anticodon aligns the tRNA carrying the corresponding amino acid for addition to the growing polypeptide chain. (Figure 4-20)

antigen Any material (usually foreign) that elicits an immune response. For B cells, an antigen elicits formation of antibody that specifically binds the same antigen; for T cells, an antigen elicits a proliferative response, followed by production of **cytokines** or the activation of cytotoxic activity.

antigen-presenting cell (APC) Any cell that can digest an antigen into small peptides and display the peptides in association with class II MHC molecules on the cell surface where they can be recognized by T cells. *Professional APCs* (dendritic cells, macrophages, and B cells) constitutively express class II MHC molecules. (Figures 24-27 and 24-28)

antiport A type of **cotransport** in which a membrane protein (*antiporter*) transports two different molecules or ions across a cell membrane in opposite directions. See also **symport**. (Figure 11-3, [3C])

apical Referring to the tip (apex) of a cell, an organ, or other body structure. In the case of epithelial cells, the apical surface is exposed to the exterior of the body or to an internal open space (e.g., intestinal lumen, duct). (Figure 19-8)

apoptosis A genetically regulated process, occurring in specific tissues during development and disease, by which a cell destroys itself; marked by the breakdown of most cell components and a series of well-defined morphological changes; also called *programmed cell death*. See also **caspases**. (Figures 1-19, 21-33, and 21-41a)

apoptosome Large, disc-shaped heptamer of mammalian Apaf-1, a protein that assembles in response to apoptosis signals and serves as an activation machine for initiator and effector **caspases**. (Figure 21-40)

aquaporins A family of **membrane transport proteins** that allow water and a few other small uncharged molecules, such as glycerol, to cross biomembranes. (Figure 11-8)

archaea Class of **prokaryotes** that constitutes one of the three distinct evolutionary lineages of modern-day organisms; also called *archaeobacteria* and *archaeans*. In some respects, archaeans are more similar to **eukaryotes** than to **bacteria** (eubacteria). (Figure 1-3)

associated constant (K_a) See **equilibrium constant**.

aster Structure composed of microtubules (astral fibers) that radiate outward from a **centrosome** during mitosis. (Figure 18-36)

asymmetric carbon atom A carbon atom bonded to four different atoms or chemical groups; also called *chiral carbon atom*. The bonds can be arranged in two different ways, producing **stereoisomers** that are mirror images of each other. (Figure 2-4)

asymmetric cell division Any cell division in which the two daughter cells receive the same genes but otherwise inherit different components (e.g., mRNAs, proteins) from the parental cell. (Figures 21-26 and 21-28)

ATP (adenosine 5'-triphosphate) A nucleotide that is the most important molecule for capturing and transferring **free energy** in cells. Hydrolysis of each of the two **phosphoanhydride bonds** in ATP releases a large amount of free energy that can be used to drive energy-requiring cellular processes. (Figure 2-31)

ATPase One of a large group of enzymes that catalyze hydrolysis of ATP to yield ADP and inorganic phosphate with release of free energy. See also Na^+/K^+ ATPase and **ATP-powered pump**.

ATP-powered pump Any transmembrane protein that has ATPase activity and couples hydrolysis of ATP to the active transport of an ion or small molecule across a biomembrane against its electrochemical gradient; often simply called *pump*. (Figure 11-9)

ATP synthase Multimeric protein complex, bound to inner mitochondrial membranes, thylakoid membranes of chloroplasts, and the bacterial plasma membrane, that catalyzes synthesis of ATP during oxidative phosphorylation and photosynthesis; also called *F_0F_1 complex*. (Figure 12-24)

autocrine Referring to signaling mechanism in which a cell produces a signaling molecule (e.g., growth factor) and then binds and responds to it.

autoradiography Technique for visualizing radioactive molecules in a sample (e.g., a tissue section or electrophoretic gel) by exposing a photographic film (emulsion) or two-dimensional electronic detector to the sample. The exposed film is called an *autoradiogram* or *autoradiograph*.

autosome Any chromosome other than a sex chromosome.

axon Long process extending from the cell body of a neuron that is capable of conducting an electric impulse (**action potential**), generated at the junction with the cell body, toward its distal, branching end (the axon terminus). (Figure 23-2)

axonal transport Motor protein-mediated transport of organelles and vesicles along microtubules in axons of nerve cells. *Anterograde* transport occurs from cell body toward axon terminal; *retrograde* transport, from axon terminal toward cell body. (Figures 18-17 and 18-18)

axoneme Bundle of **microtubules** and associated proteins present in **cilia** and **flagella** and responsible for their structure and movement. (Figure 18-29)

bacteria Class of **prokaryotes** that constitutes one of the three distinct evolutionary lineages of modern-day organisms; also called *eubacteria*. Phylogenetically distinct from **archaea** and **eukaryotes**. (Figure 1-3)

bacteriophage (phage) Any virus that infects bacterial cells. Some phages are widely used as **vectors** in **DNA cloning**.

basal See **basolateral**.

basal body Structure at the base of a **cilium** or **flagellum** from which microtubules forming the **axoneme** assemble; structurally similar to a **centriole**. (Figure 18-29)

basal lamina (pl. **basal laminae**) A thin sheet-like network of extracellular-matrix components that underlies most animal epithelia

and other organized groups of cells (e.g., muscle), separating them from connective tissue or other cells. (Figures 19-19 and 19-20)

base Any compound, often containing nitrogen, that can accept a proton (H^+) from an acid. Also, commonly used to denote the purines and pyrimidines in DNA and RNA.

base pair Association of two complementary nucleotides in a DNA or RNA molecule stabilized by hydrogen bonding between their base components. Adenine pairs with thymine or uracil (A·T, A·U) and guanine pairs with cytosine (G·C). (Figure 4-3b)

basic helix-loop-helix See **helix-loop-helix**, **basic**.

basolateral Referring to the base (basal) and side (lateral) of a polarized cell, organ, or other body structure. In the case of epithelial cells, the basolateral surface abuts adjacent cells and the underlying **basal lamina**. (Figure 19-8)

B cell A lymphocyte that matures in the bone marrow and expresses antigen-specific receptors (membrane-bound **immunoglobulin**). After interacting with antigen, a B cell proliferates and differentiates into **antibody-secreting plasma cells**.

B-cell receptor Complex composed of an antigen-specific membrane-bound immunoglobulin molecule and associated signal-transducing $Ig\alpha$ and $Ig\beta$ chains. (Figure 24-17)

benign Referring to a tumor containing cells that closely resemble normal cells. Benign tumors stay in the tissue where they originate but can be harmful due to continued growth. See also **malignant**.

beta (β) sheet A flat **secondary structure** in proteins that is created by hydrogen bonding between the backbone atoms in two different polypeptide chains or segments of a single folded chain. (Figure 3-5)

beta (β) turn A short U-shaped **secondary structure** in proteins. (Figure 3-6)

BLAST A widely used computer program for comparing the amino acid sequence of a protein with the sequences of known proteins stored in databases. BLAST searches can provide clues about the structure, function, and evolution of newly discovered proteins.

blastocyst Stage of mammalian embryo composed of ≈ 64 cells that have separated into two cell types—**trophoblast**, which will form extra-embryonic tissues, and the **inner cell mass**, which gives rise to the embryo proper; stage that implants in the uterine wall and corresponds to the **blastula** of other animal embryos. (Figure 22-1)

buffer A solution of the acid (HA) and base (A^-) form of a compound that undergoes little change in pH when small quantities of strong acid or base are added at pH values near the compound's pK_a .

cadherins A family of dimeric **cell-adhesion molecules** that aggregate in adherens junctions and desmosomes and mediate Ca^{2+} -dependent cell–cell homophilic interactions. (Figure 19-2)

calmodulin A small cytosolic regulatory protein that binds four Ca^{2+} ions. The Ca^{2+} /calmodulin complex binds to many proteins, thereby activating or inhibiting them. (Figure 3-31)

calorie A unit of heat (thermal energy). One calorie is the amount of heat needed to raise the temperature of 1 gram of water by 1 °C. The **kilocalorie** (kcal) commonly is used to indicate the energy content of foods and changes in the **free energy** of a system.

Calvin cycle The major metabolic pathway that fixes CO_2 into carbohydrates during photosynthesis; also called **carbon fixation**. It is indirectly dependent on light but can occur both in the dark and light. (Figure 12-44)

cancer General term denoting any of various malignant tumors, whose cells grow and divide more rapidly than normal, invade surrounding tissue, and sometimes spread (metastasize) to other sites.

capsid The outer proteinaceous coat of a **virus**, formed by multiple copies of one or more protein subunits and enclosing the viral nucleic acid.

carbohydrate General term for certain polyhydroxyaldehydes, polyhydroxyketones, or compounds derived from these usually having the formula $(CH_2O)_n$. Primary type of compound used for storing and supplying energy in animal cells. (Figure 2-18)

carbon fixation See **Calvin cycle**.

carcinogen Any chemical or physical agent that can cause cancer when cells or organisms are exposed to it.

caretaker gene Any gene whose encoded protein helps protect the integrity of the genome by participating in the repair of damaged DNA. Loss of function of a caretaker gene leads to increased mutation rates and promotes carcinogenesis.

caspsases A class of vertebrate protein-degrading enzymes (proteases) that function in **apoptosis** and work in a cascade with each type activating the next. (Figures 21-37 and 21-38)

catabolism Cellular degradation of complex molecules to simpler ones usually accompanied by the release of energy. **Anabolism** is the reverse process in which energy is used to synthesize complex molecules from simpler ones.

catalyst A substance that increases the rate of a chemical reaction without undergoing a permanent change in its structure. Enzymes are proteins with catalytic activity, and ribozymes are RNAs that can function as catalysts. (Figure 3-20)

cation A positively charged ion.

cDNA (complementary DNA) DNA molecule copied from an mRNA molecule by **reverse transcriptase** and therefore lacking the **introns** present in the DNA of the genome.

cell-adhesion molecules (CAMs) Proteins in the plasma membrane of cells that bind similar proteins on other cells, thereby mediating cell–cell adhesion. Four major classes of CAMs include the **cadherins**, **IgCAMs**, **integrins**, and **selectins**. (Figures 19-1 and 19-2)

cell cycle Ordered sequence of events in which a eukaryotic cell duplicates its chromosomes and divides into two. The cell cycle normally consists of four phases: G_1 before DNA synthesis occurs; S when DNA replication occurs; G_2 after DNA synthesis; and M when **cell division** occurs, yielding two daughter cells. Under certain conditions, cells exit the cell cycle during G_1 and remain in the G_0 state as nondividing cells. (Figures 1-17 and 20-1)

cell division Separation of a cell into two daughter cells. In higher eukaryotes, it involves division of the nucleus (**mitosis**) and of the cytoplasm (**cytokinesis**); mitosis often is used to refer to both nuclear and cytoplasmic division.

cell junctions Specialized regions on the cell surface through which cells are joined to each other or to the extracellular matrix. (Figure 19-9; Table 19-2)

cell line A population of cultured cells, of plant or animal origin, that has undergone a genetic change allowing the cells to grow indefinitely. (Figure 9-31b)

cell strain A population of cultured cells, of plant or animal origin, that has a finite life span and eventually dies, commonly after 25–50 generations. (Figure 9-31a)

cellulose A structural polysaccharide made of glucose units linked together by $\beta(1 \rightarrow 4)$ glycosidic bonds. It forms long microfibrils, which are the major component of the cell wall in plants.

cell wall A specialized, rigid extracellular matrix that lies next to the plasma membrane, protecting a cell and maintaining its shape; prominent in most fungi, plants, and prokaryotes, but absent in most multicellular animals. (Figure 19-37)

centriole Either of two cylindrical structures within the centrosome of animal cells and containing nine sets of triplet microtubules; structurally similar to a basal body. (Figure 18-6)

centromere DNA sequence required for proper segregation of chromosomes during mitosis and meiosis; the region of mitotic chromosomes where the kinetochore forms and that appears constricted. (Figures 6-40 and 6-46b)

centrosome (cell center) Structure located near the nucleus of animal cells that is the primary microtubule-organizing center (MTOC); it contains a pair of centrioles embedded in a protein matrix and duplicates before mitosis, with each centrosome becoming a spindle pole. (Figures 18-6 and 18-35)

chaperone Collective term for two types of proteins—*molecular chaperones* and *chaperonins*—that prevent misfolding of a target protein or actively facilitate proper folding of an incompletely folded target protein, respectively. (Figures 3-16 and 3-17)

chaperonin See **chaperone**.

checkpoint Any of several points in the eukaryotic cell cycle at which progression of a cell to the next stage can be halted until conditions are suitable. (Figure 20-35)

chemical equilibrium The state of a chemical reaction in which the concentration of all products and reactants is constant because the rates of the forward and reverse reactions are equal.

chemical potential energy The energy stored in the bonds connecting atoms in molecules.

chemiosmosis Process whereby an electrochemical proton gradient (pH plus electric potential) across a membrane is used to drive an energy-requiring process such as ATP synthesis; also called *chemiosmotic coupling*. See **proton-motive force**. (Figure 12-2)

chemokine Any of numerous small, secreted proteins that function as chemotactic cues for leukocytes.

chemotaxis Movement of a cell or organism toward or away from certain chemicals.

chimera (1) An animal or tissue composed of elements derived from genetically distinct individuals; a hybrid. (2) A protein molecule containing segments derived from different proteins.

chlorophylls A group of light-absorbing porphyrin pigments that are critical in photosynthesis. (Figure 12-31)

chloroplast A specialized organelle in plant cells that is surrounded by a double membrane and contains internal chlorophyll-

containing membranes (**thylakoids**) where the light-absorbing reactions of photosynthesis occur. (Figure 12-29)

cholesterol A lipid containing the four-ring steroid structure with a hydroxyl group on one ring; a component of many eukaryotic membranes and the precursor of steroid hormones, bile acids, and vitamin D. (Figure 10-5c)

chromatid One copy of a replicated chromosome, formed during the S phase of the cell cycle, that is joined at the centromere to the other copy; also called *sister chromatid*. During mitosis, the two chromatids separate, each becoming a chromosome of one of the two daughter cells. (Figure 6-40)

chromatin Complex of DNA, histones, and nonhistone proteins from which eukaryotic chromosomes are formed. Condensation of chromatin during mitosis yields the visible **metaphase** chromosomes. (Figures 6-28 and 6-30)

chromatography, liquid Group of biochemical techniques for separating mixtures of molecules (e.g., different proteins) based on their mass (*gel filtration chromatography*), charge (*ion-exchange chromatography*), or ability to bind specifically to other molecules (*affinity chromatography*). (Figure 3-37)

chromosome In eukaryotes, the structural unit of the genetic material consisting of a single, linear double-stranded DNA molecule and associated proteins. In most prokaryotes, a single, circular double-stranded DNA molecule constitutes the bulk of the genetic material. See also **chromatin** and **karyotype**.

cilium (pl. cilia) Short, membrane-enclosed structure extending from the surface of eukaryotic cells and containing a core bundle of microtubules. Cilia usually occur in groups and beat rhythmically to move a cell (e.g., single-celled organism) or to move small particles or fluid along a surface (e.g., trachea cells). See also **axoneme** and **flagellum**.

cisterna (pl. cisternae) Flattened membrane-bounded compartment, as found in the Golgi complex and endoplasmic reticulum.

citric acid cycle A set of nine coupled reactions occurring in the matrix of the mitochondrion in which acetyl groups are oxidized, generating CO₂ and reduced intermediates used to produce ATP; also called *Krebs cycle* and *tricarboxylic acid (TCA) cycle*. (Figure 12-10)

clathrin A fibrous protein that with the aid of assembly proteins polymerizes into a lattice-like network at specific regions on the cytosolic side of a membrane, thereby forming a clathrin-coated pit that buds off to form a vesicle. (Figure 14-18; Table 14-18)

cleavage In embryogenesis, the series of rapid cell divisions that occurs following fertilization and with little cell growth, producing progressively smaller cells; culminates in formation of the blastocyst in mammals or blastula in other animals. Also used as a synonym for the hydrolysis of molecules. (Figures 22-1 and 22-8)

cleavage/polyadenylation complex Large, multiprotein complex that catalyzes the cleavage of pre-mRNA at a 3' poly(A) site and the initial addition of adenylate (A) residues to form the poly(A) tail. (Figure 8-15)

clone (1) A population of genetically identical cells, viruses, or organisms descended from a common ancestor. (2) Multiple identical copies of a gene or DNA fragment generated and maintained via DNA cloning.

cochlea Snail-shaped structure containing the organ of Corti, the sound-sensing part of the inner ear. (Figure 23-30)

codon Sequence of three nucleotides in DNA or mRNA that specifies a particular amino acid during protein synthesis; also called *triplet*. Of the 64 possible codons, three are stop codons, which do not specify amino acids and cause termination of synthesis. (Table 4-1)

coiled coil A protein **structural motif** marked by amphipathic α helical regions that can self-associate to form stable, rodlike structures in proteins; commonly found in fibrous proteins and certain transcription factors. (Figure 3-9a)

collagen A triple-helical glycoprotein rich in glycine and proline that is a major component of the **extracellular matrix** and connective tissues. The numerous subtypes differ in their tissue distribution and the extracellular components and cell-surface proteins with which they associate. (Figure 19-22; Table 19-4)

complement A group of constitutive serum proteins that bind directly to microbial or fungal surfaces, thereby activating a proteolytic cascade that culminates in formation of the cytolytic **membrane attack complex**. (Figure 24-4).

complementary (1) Referring to two nucleic acid sequences or strands that can form perfect **base pairs** with each other. (2) Describing regions on two interacting molecules (e.g., an enzyme and its substrate) that fit together in a lock-and-key fashion.

complementary DNA (cDNA) See **cDNA**.

complementation See **genetic complementation** and **functional complementation**.

concentration gradient In cell biology, a difference in the concentration of a substance in different regions of a cell or embryo or on different sides of a cellular membrane.

conformation The precise shape of a protein or other macromolecule in three dimensions resulting from the spatial location of the atoms in the molecule. (Figure 3-8)

connexins A family of transmembrane proteins that form **gap junctions** in vertebrates. (Figure 19-18)

constitutive Referring to the continuous production or activity of a cellular molecule or the continuous operation of a cellular process (e.g., constitutive secretion) that is not regulated by internal or external signals.

contractile bundles Bundles of **actin** and **myosin** in nonmuscle cells that function in cell adhesion (e.g., *stress fibers*) or cell movement (*contractile ring* in dividing cells).

COPI A class of proteins that coat transport vesicles in the **secretory pathway**. COPI-coated vesicles move proteins from the Golgi to the endoplasmic reticulum and from later to earlier Golgi cisternae. (Table 14-1)

COPII A class of proteins that coat transport vesicles in the **secretory pathway**. COPII-coated vesicles move proteins from the endoplasmic reticulum to the Golgi. (Table 14-1)

cotranslational translocation Simultaneous transport of a secretory protein into the endoplasmic reticulum as the nascent protein is still bound to the ribosome and being elongated. (Figure 13-6)

cotransport Protein-mediated movement of an ion or small molecule across a membrane against a concentration gradient driven by coupling to movement of a second molecule down its concentration gradient in the same (**symport**) or opposite (**antiport**) direction. (Figure 11-3, [3B, C]; Table 11-1)

covalent bond Stable chemical force that holds the atoms in molecules together by sharing of one or more pairs of electrons. See also **noncovalent interaction**. (Figures 2-2 and 2-6)

cross-exon recognition complex Large assembly including RNA-binding SR proteins and other components that helps delineate exons in the **pre-mRNAs** of higher eukaryotes and assure correct **RNA splicing**. (Figure 8-13)

crossing over Exchange of genetic material between maternal and paternal **chromatids** during **meiosis** to produce recombined chromosomes. See also **recombination**. (Figure 5-10)

cyclic AMP (cAMP) A **second messenger**, produced in response to hormonal stimulation of certain G protein-coupled receptors, that activates **protein kinase A**. (Figure 15-9; Table 15-2)

cyclic GMP (cGMP) A **second messenger** that opens cation channels in rod cells and activates protein kinase G in vascular smooth muscle and other cells. (Figures 15-9, 15-18, and 15-31)

cyclin Any of several related proteins whose concentrations rise and fall during the course of the eukaryotic cell cycle. Cyclins form complexes with **cyclin-dependent kinases**, thereby activating and determining the substrate specificity of these enzymes.

cyclin-dependent kinase (CDK) A protein kinase that is catalytically active only when bound to a cyclin. Various cyclin-CDK complexes trigger progression through different stages of the eukaryotic cell cycle by phosphorylating specific target proteins. (Figure 20-32)

cytochromes A group of colored, heme-containing proteins some of which function as **electron carriers** during cellular respiration and photosynthesis. (Figure 12-14a)

cytokine Any of numerous small, secreted proteins (e.g., erythropoietin, G-CSF, interferons, interleukins) that bind to cell-surface receptors on blood and immune-system cells to trigger their differentiation or proliferation.

cytokine receptor Member of major class of cell-surface signaling receptors including those for erythropoietin, growth hormone, interleukins, and interferons. Ligand binding leads to activation of cytosolic JAK kinases associated with the receptor, thereby initiating intracellular signaling pathways. (Figures 16-8 and 16-12)

cytokinesis The division of the cytoplasm following **mitosis** to generate two daughter cells, each with a nucleus and cytoplasmic organelles. (Figure 17-34)

cytoplasm Viscous contents of a cell that are contained within the plasma membrane but, in eukaryotic cells, outside the nucleus.

cytoskeleton Network of fibrous elements, consisting primarily of **microtubules**, **microfilaments**, and **intermediate filaments**, found in the cytoplasm of eukaryotic cells. The cytoskeleton provides organization and structural support for the cell and permits directed movement of organelles, chromosomes, and the cell itself. (Figures 17-1, 17-2, and 18-1)

cytosol Unstructured aqueous phase of the cytoplasm excluding organelles, membranes, and insoluble cytoskeletal components.

cytosolic face The face of a cell membrane directed toward the cytosol. (Figure 10-8)

DAG See **diacylglycerol**.

dalton Unit of molecular mass approximately equal to the mass of a hydrogen atom (1.66×10^{-24} g).

denaturation Drastic alteration in the **conformation** of a protein or nucleic acid due to disruption of various noncovalent interactions caused by heating or exposure to certain chemicals; usually results in loss of biological function.

dendrite Process extending from the cell body of a neuron that is relatively short and typically branched and receives signals from **axons** of other neurons. (Figure 23-2)

dendritic cells Phagocytic professional **antigen-presenting cells** that reside in various tissues and can detect broad patterns of pathogen markers via their **Toll-like receptors**. After internalizing antigen at a site of tissue injury or infection, they migrate to lymph nodes and initiate activation of **T cells**. (Figure 24-6)

deoxyribonucleic acid See **DNA**.

depolarization Decrease in the cytosolic-face negative electric potential that normally exists across the plasma membrane of a cell at rest, resulting in a less inside-negative or an inside-positive **membrane potential**.

determination In embryogenesis, a change in a cell that commits the cell to a particular developmental pathway (cell fate).

development Overall process involving growth, **differentiation**, and organization by which a fertilized egg gives rise to an adult plant or animal, including the formation, growth, polarization, and movements of individual cell types, tissues, and organs.

diacylglycerol (DAG) Membrane-bound **second messenger** that can be produced by cleavage of **phosphoinositides** in response to stimulation of certain cell-surface receptors. (Figures 15-9 and 15-29)

differential gene expression The expression of different sets of genes by cells with the same genotype, resulting in production of specific sets of proteins characteristic of a particular stage of development or particular differentiated cell type. (Figure 1-24)

differentiation Process usually involving changes in gene expression by which a precursor cell becomes a distinct specialized cell type.

diploid Referring to an organism or cell having two full sets of **homologous chromosomes** and hence two copies (**alleles**) of each gene or genetic locus. Somatic cells contain the diploid number of chromosomes ($2n$) characteristic of a species. See also **haploid**.

disaccharide A small carbohydrate (sugar) composed of two monosaccharides covalently joined by a **glycosidic bond**. (Figure 2-19)

dissociation constant (K_d) See **equilibrium constant**.

disulfide bond (—S—S—) A common covalent linkage between the sulfur atoms on two cysteine residues in different polypeptides or in different parts of the same polypeptide.

DNA (deoxyribonucleic acid) Long linear polymer, composed of four kinds of deoxyribose **nucleotides**, that is the carrier of genetic information. See also **double helix, DNA** (Figure 4-3)

DNA cloning Recombinant DNA technique in which specific cDNAs or fragments of genomic DNA are inserted into a cloning

vector, which then is incorporated into cultured host cells and maintained during growth of the host cells; also called **gene cloning**. (Figure 5-14)

DNA library Collection of cloned DNA molecules consisting of fragments of the entire genome (**genomic library**) or of DNA copies of all the mRNAs produced by a cell type (**cDNA library**) inserted into a suitable cloning **vector**.

DNA ligase An enzyme that links together the 3' end of one DNA fragment with the 5' end of another, forming a continuous strand.

DNA microarray An ordered set of thousands of different nucleotide sequences arrayed on a microscope slide or other solid surface; can be used to determine patterns of gene expression in different cell types or in a particular cell type at different developmental stages or under different conditions. (Figures 5-29 and 5-30)

DNA polymerase An enzyme that copies one strand of DNA (the template strand) to make the complementary strand, forming a new double-stranded DNA molecule. All DNA polymerases add deoxyribonucleotides one at a time in the 5' → 3' direction to the 3' end of a short preexisting primer strand of DNA or RNA.

domain Distinct regions of a protein's three-dimensional structure. A **functional** domain exhibits a particular activity characteristic of the protein; a **structural** domain is ≈40 or more amino acids in length, arranged in a distinct secondary or tertiary structure; a **topological** domain has a distinctive spatial relationship to the rest of the protein.

dominant In genetics, referring to that allele of a gene expressed in the **phenotype** of a heterozygote; the nonexpressed allele is **recessive**; also refers to the phenotype associated with a dominant allele. Mutations that produce dominant alleles generally result in a gain of function. (Figure 5-2)

dominant negative In genetics, an allele that acts in a **dominant** manner but produces an effect similar to a loss of function; generally is an allele encoding a mutant protein that blocks the function of the normal protein by binding either to it or to a protein **upstream** or **downstream** of it in a pathway.

double helix, DNA The most common three-dimensional structure for cellular DNA in which the two polynucleotide strands are antiparallel and wound around each other with complementary bases hydrogen-bonded. (Figure 4-3)

downstream (1) For a gene, the direction RNA polymerase moves during transcription, which is toward the end of the template DNA strand with a 5'-hydroxyl group. Nucleotides downstream from the +1 position (the first transcribe a nucleotide) are designated +2, +3, etc. (2) Events that occur later in a cascade of steps (e.g., signaling pathway). See also **upstream**.

dyneins A class of **motor proteins** that use the energy released by ATP hydrolysis to move toward the (–) end of **microtubules**. Dyneins can transport vesicles and organelles, are responsible for the movement of cilia and flagella, and play a role in chromosome movement during mitosis. (Figures 18-24 and 18-25)

ectoderm Outermost of the three primary cell layers of the animal embryo; gives rise to epidermal tissues, the nervous system, and external sense organs. See also **endoderm** and **mesoderm**. (Figures 21-3 and 22-11)

EF hand A type of helix-loop-helix **structural motif** that occurs in many Ca^{2+} -binding proteins such as **calmodulin**. (Figure 3-9b)

electric potential The energy associated with the separation of positive and negative charges. An electric potential is maintained across the plasma membrane of nearly all cells.

electrochemical gradient The driving force that determines the energetically favorable direction of transport of an ion (or charged molecule) across a membrane. It represents the combined influence of the ion's **concentration gradient** across the membrane and the **membrane potential**.

electron carrier Any molecule or atom that accepts electrons from donor molecules and transfers them to acceptor molecules in coupled **oxidation** and **reduction** reactions. (Table 12-2)

electron transport Flow of electrons via a series of electron carriers from reduced electron donors (e.g., NADH) to O_2 in the inner mitochondrial membrane, or from H_2O to NADP^+ in the thylakoid membrane of plant chloroplasts. (Figures 12-18 and 12-30)

electron transport chain Set of four large multiprotein complexes in the inner mitochondrial membrane plus diffusible cytochrome *c* and coenzyme Q through which electrons flow from reduced electron donors (e.g., NADH) to O_2 . Each member of the chain contains one or more bound **electron carriers**. (Figure 12-16)

electrophoresis Any of several techniques for separating macromolecules based on their migration in a gel or other medium subjected to a strong electric field. (Figure 3-35)

elongation factor (EF) One of a group of nonribosomal proteins required for continued **translation** of mRNA (protein synthesis) following initiation. (Figure 4-25)

embryogenesis Early development of an individual from a fertilized egg (zygote).

embryonic stem (ES) cells A line of cultured cells derived from very early embryos that can differentiate into a wide range of cell types either in vitro or after reinsertion into a host embryo. (Figure 21-7)

endergonic Referring to reactions and processes that have a positive ΔG and thus require an input of **free energy** in order to proceed; opposite of **exergonic**.

endocrine Referring to signaling mechanism in which target cells bind and respond to a **hormone** released into the blood by distant specialized secretory cells usually present in a gland (e.g., pituitary or thyroid gland).

endocytic pathway Cellular pathway involving **receptor-mediated endocytosis** that internalizes extracellular materials too large to be imported by membrane transport proteins and to remove receptor proteins from the cell surface as a way to down-regulate their activity. (Figure 14-29)

endocytosis General term for uptake of extracellular material by invagination of the plasma membrane; includes **receptor-mediated endocytosis**, **phagocytosis**, and **pinocytosis**.

endoderm Innermost of the three primary cell layers of the animal embryo; gives rise to the gut and most of the respiratory tract. See **ectoderm** and **mesoderm**. (Figures 21-3 and 22-11)

endoplasmic reticulum (ER) Network of interconnected membranous structures within the cytoplasm of eukaryotic cells contiguous with the outer nuclear envelope. The **rough ER**, which is

associated with **ribosomes**, functions in the synthesis and processing of secreted and membrane proteins; the **smooth ER**, which lacks ribosomes, functions in lipid synthesis. (Figure 9-1)

endosome One of two types of membrane-bounded compartments: **early endosomes** (or endocytic vesicles), which bud off from the plasma membrane during receptor-mediated endocytosis, and **late endosomes**, which have an acidic internal pH and function in sorting of proteins to **lysosomes**. (Figures 14-1 and 14-29)

endosymbiont Bacterium that resides inside a eukaryotic cell in a mutually beneficial partnership. According to the endosymbiont hypothesis, both mitochondria and chloroplasts evolved from endosymbionts. (Figure 6-20)

endothermic Referring to reactions and processes that have a positive change in **enthalpy**, ΔH , and thus must absorb heat in order to proceed; opposite of **exothermic**.

enhancer A regulatory sequence in eukaryotic DNA that may be located at a great distance from the gene it controls or even within the coding sequence. Binding of specific proteins to an enhancer modulates the rate of transcription of the associated gene. (Figure 7-16)

enhancesome Large nucleoprotein complex that assembles from transcription factors (activators and repressors) as they bind cooperatively to their binding sites in an **enhancer** with the assistance of DNA-bending proteins. (Figure 7-30)

enthalpy (*H*) Heat; in a chemical reaction, the enthalpy of the reactants or products is equal to their total bond energies.

entropy (*S*) A measure of the degree of disorder or randomness in a system; the higher the entropy, the greater the disorder.

envelope See **nuclear envelope** or **viral envelope**.

enzyme A protein that catalyzes a particular chemical reaction involving a specific **substrate** or small number of related substrates.

Eph Cell-surface receptor for an **ephrin**; also called *Eph receptor*.

ephrins A family of membrane-bound signaling proteins that participate in cell-cell interactions involved in regulating the growth of axons so that they make the proper connections during development of the nervous system.

epidermal growth factor (EGF) One of a family of secreted signaling proteins (the *EGF family*) that is used in the development of most tissues in most or all animals. EGF signals are bound by **receptor tyrosine kinases**. Mutations in EGF signal-transduction components are implicated in human cancer, including brain cancer. See **HER family**.

epigenetic Referring to a process that affects the expression of specific genes and is inherited by daughter cells, but does not involve a change in DNA sequence.

epinephrine A catecholamine secreted by the adrenal gland and some neurons in response to stress; also called *adrenaline*. It functions as both a hormone and neurotransmitter, mediating "fight or flight" responses (e.g., increased blood glucose levels and heart rate).

epithelium (pl. **epithelia**) Sheetlike covering, composed of one or more layers of tightly adhering cells, on external and internal body surfaces. (Figure 19-8)

epitope The part of an antigen molecule that binds to an antigen-specific receptor on B or T cells or to antibody. Large protein antigens usually possess multiple epitopes that bind to antibodies of different specificity.

equilibrium constant (K) Ratio of forward and reverse rate constants for a reaction. For a binding reaction, $A + B \rightleftharpoons AB$, the association constant (K_a) equals K , and the dissociation constant (K_d) equals $1/K$.

erythropoietin (Epo) A cytokine that triggers production of red blood cells by inducing the proliferation and differentiation of erythroid progenitor cells in the bone marrow. (Figures 16-6 and 21-5)

euchromatin Less condensed portions of **chromatin** present in interphase chromosomes; includes most transcriptionally active regions. See also **heterochromatin**. (Figure 6-33a)

eukaryotes Class of organisms, composed of one or more cells containing a membrane-enclosed nucleus and organelles, that constitutes one of the three distinct evolutionary lineages of modern-day organisms; also called *eukarya*. Includes all organisms except viruses and prokaryotes. (Figure 1-3)

excision-repair system, DNA One of several mechanisms for repairing DNA damage due to spontaneous depurination or deamination or exposure to **carcinogens**. These repair systems normally operate with a high degree of fidelity and their loss is associated with increased risk for certain cancers.

exergonic Referring to reactions and processes that have a negative ΔG and thus release **free energy** as they proceed; opposite of **endergonic**.

exocytosis Release of intracellular molecules (e.g., hormones, matrix proteins) contained within a membrane-bounded vesicle by fusion of the vesicle with the plasma membrane of a cell.

exon Segment of a eukaryotic gene (or of its **primary transcript**) that reaches the cytoplasm as part of a mature mRNA, rRNA, or tRNA molecule. See also **intron**.

exon shuffling Evolutionary process for creating new genes (i.e., new combinations of exons) from preexisting ones by recombination between introns of two separate genes or by transposition of mobile DNA elements. (Figures 6-18 and 6-19)

exoplasmic face The face of a cell membrane directed away from the cytosol. (Figure 10-8)

exosome Large exonuclease-containing complex that degrades spliced out introns and improperly processed pre-mRNAs in the nucleus or mRNAs with shortened poly(A) tails in the cytoplasm. (Figure 8-1)

exothermic Referring to reactions and processes that have a negative change in **enthalpy**, ΔH , and thus release heat as they proceed; opposite of **endothermic**.

exportin Protein that binds a “cargo” protein in the nucleus and with the aid of Ran (a member of the **GTPase superfamily**) transports the cargo through a nuclear pore complex to the cytoplasm. See also **importin**. (Figure 13-36)

expression vector A modified **plasmid** or virus that carries a gene or cDNA into a suitable host cell and there directs synthesis of the encoded protein; used to screen a DNA library for a gene of interest or to produce large amounts of a protein from its cloned gene (Figures 5-31 and 5-32)

extracellular matrix (ECM) A complex interdigitating meshwork of proteins and polysaccharides secreted by cells into the spaces between them. It provides structural support in tissues and can affect the development and biochemical functions of cells. (Table 19-1)

F₀F₁ complex See **ATP synthase**.

facilitated transport Protein-aided transport of an ion or small molecule across a cell membrane down its concentration gradient at a rate greater than that obtained by **simple diffusion**; also called *facilitated diffusion*. (Table 11-1)

FACS See **fluorescence-activated cell sorter**.

FAD (flavin adenine dinucleotide) A small organic molecule that functions as an electron carrier by accepting two electrons from a donor molecule and two H⁺ from the solution. (Figure 2-33b)

fatty acid Any long hydrocarbon chain that has a carboxyl group at one end; a major source of energy during metabolism and a precursor for synthesis of phospholipids, triglycerides, and cholesteryl esters. (Figure 2-21; Table 2-4)

fibroblast A common type of connective tissue cell that secretes **collagen** and other components of the **extracellular matrix**; migrates and proliferates during wound healing and in tissue culture.

fibronectin An abundant **multiadhesive matrix protein** that occurs in numerous isoforms, generated by alternative splicing, in various cell types. Binds many other components of the extracellular matrix and to integrin adhesion receptors. (Figure 19-30)

FISH See **fluorescence in situ hybridization**.

flagellum (pl. flagella) Long locomotory structure (usually one per cell) extending from the surface of some eukaryotic cells (e.g., sperm), whose whiplike bending propels the cell through a fluid medium. Bacterial flagella are smaller and much simpler structures. See also **axoneme** and **cilium**. (Figure 18-30)

flavin adenine dinucleotide See **FAD**.

flippase Protein that facilitates the movement of membrane lipids from one leaflet to the other leaflet of a phospholipid bilayer. (Figure 11-15)

fluorescence-activated cell sorter (FACS) An instrument that can detect one or a few cells from thousands of other cells and sort them based on differences in their fluorescence. (Figure 9-28)

fluorescence in situ hybridization (FISH) Any of several related techniques for detecting specific DNA or RNA sequences in cells and tissues by treating samples with fluorescent **probes** that hybridize to the sequence of interest and observing the samples by fluorescence microscopy.

fluorescent staining General technique for visualizing cellular components by treating cells or tissues with a fluorescent dye-labeled agent (e.g., antibody) that binds specifically to a component of interest and observing the sample by fluorescence microscopy.

free energy (G) A measure of the potential energy of a system, which is a function of the **enthalpy** (H) and **entropy** (S).

free-energy change (ΔG) The difference in the total free energy of the product molecules and starting molecules (reactants) in a

chemical reaction. A large negative value of ΔG indicates that a reaction (or other process) has a strong tendency to occur.

functional complementation Procedure for screening a DNA library to identify the wild-type gene that restores the function of a defective gene in a particular mutant. (Figure 5-18)

G₀, G₁, G₂ phase See cell cycle.

gamete Specialized **haploid** cell (in animals either a sperm or an egg) produced by **meiosis** of precursor **germ cells**; in sexual reproduction, union of a sperm and an egg initiates the development of a new individual.

gap genes In *Drosophila*, a group of genes that are activated in the early embryo by transcription factors produced from maternal mRNAs in the zygote; all encode transcription factors that function in early patterning along the anteroposterior axis. (Figure 22-27a, b)

gap junction Protein-lined channel connecting the cytoplasm of adjacent animal cells that allows passage of ions and small molecules between the cells. See also **plasmodesmata**. (Figure 19-18)

gastrulation Process in early animal embryos in which cells of the blastocyst invaginate, giving rise to the three **germ layers**, ectoderm, mesoderm, and endoderm. (Figure 22-11)

gene Physical and functional unit of heredity, which carries information from one generation to the next. In molecular terms, it is the entire DNA sequence—including **exons**, **introns**, and **transcription-control regions**—necessary for production of a functional polypeptide or RNA. See also **transcription unit**.

gene control All of the mechanisms involved in regulating **gene expression**. Most common is regulation of transcription, although mechanisms influencing the processing, stabilization, and translation of mRNAs help control expression of some genes.

gene expression Overall process by which the information encoded in a gene is converted into an observable **phenotype** (most commonly production of a protein).

gene family Set of genes that arose by duplication of a common ancestral gene and subsequent divergence due to small changes in the nucleotide sequence. (Figure 6-26)

genetic code The set of rules whereby nucleotide triplets (**codons**) in DNA or RNA specify amino acids in proteins. (Table 4-1)

genetic complementation Restoration of a wild-type function in diploid heterozygous cells generated from haploid cells, each of which carries a mutation in a different gene whose encoded protein is required for the same biochemical pathway. Complementation analysis can determine if recessive mutations in two mutants with the same mutant phenotype are in the same or different genes. (Figure 5-7)

genetic mapping Determination of the relative position of genes on a chromosome.

genetic markers Alleles associated with an easily detectable **phenotype** that are used experimentally to identify or select for a linked gene, a chromosome, a cell, or an individual. See also **molecular markers**, **DNA-based**.

genome Total genetic information carried by a cell or organism.

genomic imprinting Process that occurs during development of gametes involving chromatin modifications so that only certain genes can subsequently be expressed. Because different genes are imprinted in male and female gametes, the phenotypic expression of certain genes is determined by whether a particular allele is inherited from the female or male parent.

genomics Comparative analyses of the complete genomic sequences from different organisms and determination of global patterns of gene expression; used to assess evolutionary relations among species and to predict the number and general types of RNAs produced by an organism.

genotype Entire genetic constitution of an individual cell or organism, usually with emphasis on the particular alleles at one or more specific loci.

germ cell In sexually reproducing organisms, any cell that can potentially contribute to the formation of offspring including gametes and their immature precursors; also called **germ-line cell**. See also **somatic cell**.

germ layers Three primary cell layers—ectoderm, endoderm, and mesoderm—formed during gastrulation of animal embryos that give rise to distinct tissues and organs. (Figure 21-3)

germ line Lineage of germ cells, which give rise to **gametes** and thus participate in formation of the next generation of organisms; also, the genetic material transmitted from one generation to the next through the gametes.

germ-line cell See **germ cell**.

glia Supporting cells of nervous tissue that, unlike neurons, do not conduct electrical impulses; also called **glial cells**. Of the four types, *Schwann cells* and *oligodendrocytes* produce **myelin sheaths**; *astrocytes* function in **synapse** formation; and *microglia* make **trophic factors** and serve in immune responses. (Figure 23-14)

glucagon A peptide hormone produced in the cells of pancreatic islets that triggers the conversion of glycogen to glucose by the liver; acts with **insulin** to control blood glucose levels.

glucose Six-carbon monosaccharide (sugar) that is the primary metabolic fuel in most cells. The large glucose polymers, glycogen and starch, are used to store energy in animal cells and plant cells, respectively.

GLUT proteins A family of transmembrane proteins, containing 12 membrane-spanning α helices, that transport glucose (and a few other sugars) across cell membranes down its concentration gradient. (Figure 11-5)

glycogen A very long, branched polysaccharide, composed exclusively of glucose units, that is the primary storage carbohydrate in animals; found primarily in liver and muscle cells.

glycolipid Any lipid to which a short carbohydrate chain is covalently linked; commonly found in the plasma membrane.

glycolysis Metabolic pathway in which sugars are degraded anaerobically to lactate or pyruvate in the cytosol with the production of ATP. (Figure 12-3)

glycoprotein Any protein to which one or more oligosaccharide chains are covalently linked. Most secreted proteins and many membrane proteins are glycoproteins.

glycosaminoglycan (GAG) A long, linear, highly charged polymer of a repeating disaccharides in which many residues often are

sulfated. GAGs are major components of the extracellular matrix, usually as components of **proteoglycans**. (Figure 19-26)

glycosidic bond The covalent linkage between two monosaccharide residues formed when a carbon atom in one sugar reacts with a hydroxyl group on a second sugar with the net release of a water molecule (dehydration). (Figure 2-13)

G protein, monomeric (small). See **GTPase superfamily**.

G protein, trimeric (large) Any of numerous heterotrimeric GTP-binding switch proteins that function in intracellular signaling pathways; usually activated by ligand binding to a coupled seven-spanning receptor on the cell surface. See also **GTPase superfamily**. (Table 15-1)

G protein-coupled receptor (GPCR) Member of a large class of cell-surface signaling receptors, including those for epinephrine, glucagon, and yeast mating factors. All GPCRs contain seven transmembrane α helices. Ligand binding leads to activation of a coupled trimeric G protein, thereby initiating intracellular signaling pathways. (Figures 15-10 and 15-13)

Golgi complex Stacks of flattened, interconnected membrane-bounded compartments (cisternae) in eukaryotic cells that function in processing and sorting of proteins and lipids destined for other cellular compartments or for secretion; also called *Golgi apparatus*. (Figure 9-6)

growth cone Bulbous enlargement, composed of cell membrane extensions, at the leading, growing end of an **axon**; functions as a moving sensory guidance structure. (Figures 23-37 and 23-38)

growth factor An extracellular polypeptide molecule that binds to a cell-surface receptor, triggering an intracellular signaling pathway generally leading to cell proliferation.

GTPase superfamily Group of intracellular switch proteins that cycle between an inactive state with bound GDP and an active state with bound GTP. Includes the G_{α} subunit of trimeric (large) G proteins, monomeric (small) G proteins (e.g., **Ras**, **Rab**, **Ran**, and **Rac**), and certain **elongation factors** used in protein synthesis. See also **G protein, trimeric (large)**. (Figure 3-32)

haploid Referring to an organism or cell having only one member of each pair of **homologous chromosomes** and hence only one copy (**allele**) of each gene or genetic locus. Gametes and bacterial cells are haploid. See also **diploid**.

Hedgehog (Hh) A family of secreted signaling proteins that are important regulators of the development of most tissues and organs in diverse animal species. Mutations in Hh signal-transduction components are implicated in human cancer and birth defects. The receptor is the Patched transmembrane protein. (Figures 16-33 and 16-34)

helicase (1) Any enzyme that moves along a DNA duplex using the energy released by ATP hydrolysis to separate (unwind) the two strands; required for DNA replication. (2) Activity of certain initiation factors that can unwind the secondary structures in mRNA during initiation of translation.

helix-loop-helix, basic (bHLH) A conserved DNA-binding **structural motif**, consisting of two α helices connected by a short loop, that is found in many dimeric eukaryotic transcription factors. (Figure 7-26b)

HER family Group of receptors, belonging to the **receptor tyrosine kinase (RTK)** class, that bind to members of the epidermal growth factor (EGF) family of signaling molecules in humans. Overexpression of HER2 protein is associated with some breast cancers. (Figure 16-18)

heterochromatin Regions of **chromatin** that remain highly condensed and transcriptionally inactive during interphase. (Figure 6-33a)

heterozygous Referring to a diploid cell or organism having two different **alleles** of a particular gene.

hexose A six-carbon **monosaccharide**.

high-energy bond Covalent bond that releases a large amount of energy when hydrolyzed under the usual intracellular conditions. Examples include the phosphoanhydride bonds in ATP, thioester bond in acetyl CoA, and various phosphate ester bonds.

histone One of several small, highly conserved basic proteins, found in the **chromatin** of all eukaryotic cells, that associate with DNA in the **nucleosome**. (Figure 6-29)

homeodomain Conserved DNA-binding **structural motif** (a helix-turn-helix) found in many developmentally important transcription factors.

homeosis Transformation of one body part into another arising from mutation in or misexpression of certain developmentally critical genes. (Figure 22-31)

homologous chromosome One of the two copies of each morphologic type of chromosome present in a **diploid** cell; also called **homolog**. Each homolog is derived from a different parent.

homologous recombination See **recombination**.

homologs Maternal and paternal copies of each morphologic type of chromosome present in a diploid cell; also called *homologues*.

homology Similarity in characteristics (e.g., protein and nucleic acid sequences or the structure of an organ) that reflects a common evolutionary origin. Proteins or genes that exhibit homology are said to be homologous and sometimes are called homologs. In contrast, *analogy* is a similarity in structure or function that does not reflect a common evolutionary origin.

homozygous Referring to a diploid cell or organism having two identical **alleles** of a particular gene.

hormone Generally, any extracellular substance that induces specific responses in target cells; specifically, those signaling molecules that circulate in the blood and mediate **endocrine** signaling.

Hox genes Group of developmentally important genes that encode homeodomain-containing transcription factors and help determine the body plan in animals. Mutations in Hox genes often cause **homeosis**. (Figure 22-32).

hyaluronan A large, highly hydrated **glycosaminoglycan (GAG)** that is a major component of the extracellular matrix; also called *hyaluronic acid* and *hyaluronate*. It imparts stiffness and resilience as well as a lubricating quality to many types of connective tissue. (Figure 19-26a)

hybridization, nucleic acid Association of two **complementary** nucleic acid strands to form double-stranded molecules, which can contain two DNA strands, two RNA strands, or one DNA

and one RNA strand. Used experimentally in various ways to detect specific DNA or RNA sequences.

hybridoma A clone of hybrid cells that are immortal and produce **monoclonal antibody**; formed by fusion of a normal antibody-producing B cell with a myeloma cell. (Figure 9-35)

hydrocarbon Any compound containing only carbon and hydrogen atoms.

hydrogen bond A **noncovalent interaction** between an atom (commonly oxygen or nitrogen) carrying a partial negative charge and a hydrogen atom carrying a partial positive charge. Important in stabilizing the conformation of proteins and in formation of **base pairs** between nucleic acid strands. (Figure 2-8)

hydrophilic Interacting effectively with water. See also **polar**.

hydrophobic Not interacting effectively with water; in general, poorly soluble or insoluble in water. See also **nonpolar**.

hydrophobic effect The tendency of nonpolar molecules or parts of molecules to associate with each other in aqueous solution so as to minimize their direct interactions with water; commonly called a *hydrophobic interaction* or *bond*. (Figure 2-11)

hyperpolarization Increase in the magnitude of the cytosolic-negative electric potential that normally exists across the plasma membrane of a cell at rest, resulting in a more negative **membrane potential**.

hypertonic Referring to an external solution whose solute concentration is high enough to cause water to move out of cells due to **osmosis**.

hypotonic Referring to an external solution whose solute concentration is low enough to cause water to move into cells due to **osmosis**.

IgCAMs A family of **cell-adhesion molecules** that contain multiple immunoglobulin (Ig) domains and mediate Ca^{2+} -independent cell–cell interactions. IgCAMs are produced in a variety of tissues and are components of **tight junctions**. (Figure 19-2)

immunity State of being resistant (immune) against the harmful effects of exposure to pathogens either in the form of *innate* responses, which develop within minutes to hours but are relatively nonspecific, or *adaptive* responses, which take several days to develop fully but are highly specific. (Figure 24-1)

immunoglobulin (Ig) Any of the serum proteins, produced by fully differentiated **B cells**, that can function as antibodies; also occur in membrane-bound form as part of the **B-cell receptor**. Immunoglobulins are divided into five main classes (*isotypes*) that exhibit distinct functional properties. See also **antibody**. (Figures 24-8 and 24-9)

immunoglobulin (Ig) fold Evolutionarily ancient structural motif found in antibodies, the T-cell receptor, and numerous other eukaryotic proteins not directly involved in antigen-specific recognition; also called *Ig domain*. (Figure 24-12b)

importin Protein that binds a “cargo” protein in the cytoplasm and transports the cargo through a nuclear pore complex into the nucleus. Return of importin to the cytoplasm requires the aid of Ran (a member of the **GTPase superfamily**) See also **exportin**. (Figure 13-35)

induction (1) In embryogenesis, a change in the developmental fate of one cell or tissue caused by signals from another cell or tissue or by direct contact. (2) In metabolism, an increase in the synthesis of an enzyme or series of enzymes mediated by a specific molecule (**inducer**).

inflammation Localized response to injury or infection that leads to the activation of immune-system cells and their recruitment to the affected site; marked by the four classical signs of redness, swelling, heat, and pain. (Figure 24-6)

initiation factor (IF) One of a group of nonribosomal proteins that promote the proper association of ribosomes and mRNA and are required for initiation of **translation** (protein synthesis). (Figure 4-24)

inositol 1,4,5-trisphosphate (IP₃) Intracellular **second messenger** produced by cleavage of the membrane lipid phosphatidylinositol 4,5-bisphosphate in response to stimulation of certain cell-surface receptors. IP₃, which triggers release of Ca^{2+} stored in the endoplasmic reticulum, is one of several biologically active **phosphoinositides**. (Figure 15-9; Table 15-3)

in situ hybridization Any technique for detecting specific DNA or RNA sequences in cells and tissues by treating samples with single-stranded RNA or DNA **probes** that hybridize to the sequence of interest. (Figure 5-28)

insulator DNA sequence that prevents transcriptional **enhancers** on one side of the insulator from influencing transcription of a gene on the other side of the insulator, thereby preventing inappropriate interactions between the control elements of neighboring genes.

insulin A protein hormone produced in the β cells of the pancreatic islets that stimulates uptake of glucose into muscle and fat cells; acts with **glucagon** to help regulate blood glucose levels. Insulin also functions as a growth factor for many cells.

integral membrane protein Any protein that contains one or more hydrophobic segments embedded within the core of the **phospholipid bilayer**; also called *transmembrane protein*. (Figure 13-10)

integrins A large family of heterodimeric transmembrane proteins that function as adhesion receptors, promoting cell–matrix adhesion, or as cell-adhesion molecules, promoting cell–cell adhesion. (Table 19-3)

interferons (IFNs) Small group of cytokines that bind to cell-surface receptors on target cells inducing changes in gene expression that lead to an antiviral state or other cellular responses important in immune responses.

interleukins (ILs) Large group of cytokines, some released in response to inflammation, that promote proliferation and functioning of T cells and antibody-producing B cells of the immune system.

intermediate filament Cytoskeletal fiber (10 nm in diameter) formed by polymerization of related, but tissue-specific, subunit proteins including **keratins**, **lamins**, and **neurofilaments**. (Figure 18-45; Table 18-1)

interphase Long period of the cell cycle, including the G₁, S, and G₂ phases, between one M (mitotic) phase and the next. (Figures 1-17 and 20-1)

intron Part of a **primary transcript** (or the DNA encoding it) that is removed by splicing during RNA processing and is not included in the mature, functional mRNA, rRNA, or tRNA.

in vitro Denoting a reaction or process taking place in an isolated cell-free extract; sometimes used to distinguish cells growing in culture from those in an organism.

in vivo Denoting a reaction or process that occurs in an intact cell or organism.

ionic interaction A **noncovalent interaction** between a positively charged ion (cation) and negatively charged ion (anion); commonly called *ionic bond*.

IP₃ See **inositol 1,4,5-trisphosphate**.

isoelectric point (pI) The pH of a solution at which a dissolved protein or other potentially charged molecule has a net charge of zero and therefore does not move in an electric field. (Figure 3-36)

isoform One of several forms of the same protein whose amino acid sequences differ slightly and whose general activities are similar. Isoforms may be encoded by different genes or by a single gene whose primary transcript undergoes **alternative splicing**.

isotonic Referring to a solution whose solute concentration is such that it causes no net movement of water in or out of cells.

karyopherin One of a family of nuclear transport proteins that functions as an **importin**, **exportin**, or occasionally both. Each karyopherin binds to a specific signal sequence in cargo proteins moving in or out of the nucleus.

karyotype Number, sizes, and shapes of the entire set of **metaphase** chromosomes of a eukaryotic cell. (Chapter 6 opening figure)

keratins A group of **intermediate filament** proteins found in epithelial cells that assemble into heteropolymeric filaments. (Figure 18-46)

kilocalorie (kcal) See **calorie**.

kinase An enzyme that transfers the terminal (γ) phosphate group from ATP to a substrate. Protein kinases, which phosphorylate specific serine, threonine, or tyrosine residues, play a critical role in regulating the activity of many cellular proteins. See also **phosphatases**. (Figure 3-33)

kinesins A class of **motor proteins** that use energy released by ATP hydrolysis to move toward the (+) end of a **microtubule**. Kinesins can transport vesicles and organelles and play a role in chromosome movement during mitosis. (Figures 18-19 through 18-21).

kinetic energy Energy of movement, such as the motion of molecules.

kinetochore A multilayer protein structure located at or near the **centromere** of each mitotic chromosome from which microtubules extend toward the spindle poles of the cell; plays an active role in movement of chromosomes toward the poles during anaphase. (Figure 18-39)

K_m A parameter that describes the affinity of an enzyme for its substrate and equals the substrate concentration that yields the half-maximal reaction rate; also called the *Michaelis constant*. A similar parameter describes the affinity of a transport protein for the transported molecule or the affinity of a receptor for its ligand. (Figure 3-22)

knockdown, siRNA Technique for experimentally inhibiting translation of a specific mRNA by use of siRNA; useful for reducing the activity of a protein, particularly in organisms that are not amenable to classical genetic methods for isolating loss-of-function mutants.

knockout, gene Selective inactivation of a specific gene by replacing it with a nonfunctional (disrupted) allele in an otherwise normal organism.

lagging strand One of the two daughter DNA strands formed at a **replication fork** as short, discontinuous segments (Okazaki fragments), which are synthesized in the 5' → 3' direction and later joined. See also **leading strand**. (Figure 4-30)

laminin Large heterotrimeric **multiadhesive matrix protein** that is found in all **basal lamina**. (Figure 19-21)

lamins A group of **intermediate filament** proteins that form a fibrous network, the **nuclear lamina**, on the inner surface of the nuclear envelope.

lateral See **basolateral**.

lateral inhibition Important signal-mediated developmental process that results in adjacent equivalent or near-equivalent cells assuming different fates. (Figure 22-41)

leading strand One of the two daughter DNA strands formed at a **replication fork** by continuous synthesis in the 5' → 3' direction. The direction of leading-strand synthesis is the same as movement of the replication fork. See also **lagging strand**. (Figure 4-30)

lectin Any protein that binds tightly to specific sugars. Lectins assist in the proper folding of some glycoproteins in the endoplasmic reticulum, and can be used in affinity chromatography to purify glycoproteins or as reagents to detect them in situ.

leucine zipper A type of coiled-coil **structural motif** composed of two α helices that form specific homo- or heterodimers; common motif in many eukaryotic transcription factors. See **coiled coil**. (Figures 7-26a and 3-9)

ligand Any molecule, other than an enzyme **substrate**, that binds tightly and specifically to a macromolecule, usually a protein, forming a macromolecule–ligand complex.

LINEs (long interspersed elements) Class of **retrotransposons**, ≈ 6 kb long, that are particularly abundant in mammals and constitute about 21 percent of total human DNA. (Figure 6-16).

linkage In genetics, the tendency of two different loci on the same chromosome to be inherited together. The closer two loci are, the lower the frequency of **recombination** between them and the greater their linkage.

lipid Any organic molecule that is poorly soluble or virtually insoluble in water but is soluble in nonpolar organic solvents. Major classes include **fatty acids**, **phospholipids**, **steroids**, and **triglycerides**.

lipid-anchored membrane protein Any protein that is tethered to a cellular membrane by one or more covalently attached lipid groups, which are embedded in the phospholipid bilayer. (Figure 10-19)

lipid raft Microdomain in the plasma membrane that is enriched in cholesterol, sphingomyelin, and certain proteins.

lipoprotein Any large, water-soluble protein and lipid complex that functions in mass transfer of lipids throughout the body. See also **low-density lipoprotein (LDL)**.

liposome Artificial spherical **phospholipid bilayer** structure with an aqueous interior that forms in vitro from phospholipids and may contain membrane proteins. (Figure 10-6c)

locus (pl. loci) In genetics, the specific site of a gene on a chromosome. All the **alleles** of a particular gene occupy the same locus.

long terminal repeats (LTRs) Direct repeat sequences, containing up to 600 base pairs, that flank the coding region of integrated retroviral DNA and viral **retrotransposons**.

low-density lipoprotein (LDL) A class of **lipoprotein**, containing apolipoprotein B-100, that is a primary transporter of cholesterol in the form of cholesteryl esters between tissues, especially to the liver. (Figure 14-27)

lumen The space within a tubular structure (e.g., a vessel or the intestine) or the interior volume of a membrane-bounded compartment within a cell.

lymphocytes Two classes of white blood cells that can recognize foreign molecules (**antigens**) and mediate immune responses. B lymphocytes (B cells) are responsible for production of antibodies; T lymphocytes (T cells) are responsible for destroying virus- and bacteria-infected cells, foreign cells, and cancer cells.

lysis Destruction of a cell by rupture of the plasma membrane and release of the contents.

lysogeny Phenomenon in which the DNA of a bacterial virus (bacteriophage) is incorporated into the host-cell genome and replicated along with the bacterial DNA but is not expressed. Subsequent activation leads to formation of new viral particles, eventually causing lysis of the cell.

lysosome Small organelle that has an internal pH of 4–5, contains hydrolytic enzymes, and functions in degradation of materials internalized by endocytosis and of cellular components in autophagy. (Figure 9-2)

M (mitotic) phase See **cell cycle**.

macromolecule Any large, usually polymeric molecule (e.g., a protein, nucleic acid, polysaccharide) with a molecular mass greater than a few thousand daltons.

macrophages Phagocytic leukocytes that can detect broad patterns of pathogen markers via **Toll-like receptors**. They function as professional **antigen-presenting cells** and are a major source of **cytokines**.

major histocompatibility complex (MHC) Set of adjacent genes that encode class I and class II **MHC molecules** and other proteins required for antigen presentation, as well as some complement proteins; called the *H-2 complex* in mice and the *HLA complex* in humans. (Figure 24-21)

malignant Referring to a tumor or tumor cells that can invade surrounding normal tissue and/or undergo **metastasis**. See also **benign**.

MAP kinase Any of a family of protein kinases that are activated in response to cell stimulation by many different growth factors and that mediate cellular responses by phosphorylating

specific transcription factors and other target proteins. (Figures 16-26 and 16-27)

maximal velocity See V_{\max} .

mechanosensor Any of several types of sensory structures that are embedded in various tissues and respond to touch, the positions and movements of the limbs and head, pain, and temperature.

mediator A very large multiprotein complex that forms a molecular bridge between transcriptional activators bound to an **enhancer** and to RNA polymerase II bound at a **promoter**; functions as a co-activator in stimulating transcription. (Figures 7-41 and 7-42)

meiosis In eukaryotes, a special type of cell division that occurs during maturation of germ cells; comprises two successive nuclear and cellular divisions with only one round of DNA replication. Results in production of four genetically nonequivalent haploid cells (**gametes**) from an initial diploid cell. (Figure 5-3)

membrane potential Electric potential difference, expressed in volts, across a membrane due to the slight excess of positive ions (cations) on one side and negative ions (anions) on the other. (Figures 11-17 and 11-18)

membrane transport protein Collective term for any integral membrane protein that mediates movement of one or more specific ions or small molecules across a cellular membrane regardless of the transport mechanism. (Figure 11-3)

meristem Organized group of undifferentiated, dividing cells that are maintained at the tips of growing shoots and roots in plants. All the adult structures arise from meristems.

mesenchyme Immature embryonic connective tissue, composed of loosely organized and loosely attached cells, derived from either the **mesoderm** or **ectoderm** in animals.

mesoderm The middle of the three primary cell layers of the animal embryo, lying between the **ectoderm** and **endoderm**; gives rise to the notochord, connective tissue, muscle, blood, and other tissues. (Figures 21-3 and 22-11)

messenger RNA See **mRNA**.

metaphase Stage of mitosis at which condensed chromosomes are aligned equidistant between the poles of the mitotic spindle, but have not yet started to segregate toward the spindle poles. (Figure 18-34)

metastasis Spread of cancer cells from their site of origin and establishment of areas of secondary growth.

MHC See **major histocompatibility complex**.

MHC molecules Glycoproteins that display peptides, derived from foreign (and self) proteins, on the surface of cells and are required for antigen presentation to **T cells**. *Class I* molecules are expressed constitutively by nearly all nucleated cells; *class II* molecules, by professional antigen-presenting cells. (Figures 24-23 and 24-24)

micelle A water-soluble spherical aggregate of phospholipids or other amphipathic molecules that form spontaneously in aqueous solution. (Figure 10-6c)

Michaelis constant See K_m .

microfilament Cytoskeletal fiber (≈ 7 nm in diameter) that is formed by polymerization of monomeric globular (G) **actin**; also called *actin filament*. Microfilaments play an important role in

muscle contraction, cytokinesis, cell movement, and other cellular functions and structures. (Figure 17-4)

micro RNA See **miRNA**.

microtubule Cytoskeletal fiber (≈ 25 nm in diameter) that is formed by polymerization of α , β -**tubulin** monomers and exhibits structural and functional polarity. Microtubules are important components of cilia, flagella, the mitotic spindle, and other cellular structures. (Figures 18-2 and 18-3)

microtubule-associated protein (MAP) Any protein that binds to microtubules and regulates their stability. (Figures 18-14 and 18-15)

microtubule-organizing center See **MTOC**.

microvillus (pl. **microvilli**) Small, membrane-covered projection on the surface of an animal cell containing a core of actin filaments. Numerous microvilli are present on the absorptive surface of intestinal epithelial cells, increasing the surface area for transport of nutrients. (Figures 17-4 and 19-9)

miRNA (micro RNA) Any of numerous small, endogenous cellular RNAs, 20–30 nucleotides long, that are processed from double-stranded regions of hairpin secondary structures in long precursor RNAs. A single strand of the mature miRNA associates with several proteins to form an RNA-induced silencing complex (**RISC**) that inhibits translation of a target mRNA to which the miRNA hybridizes imperfectly. Several miRNAs must hybridize to a single mRNA to inhibit its translation. See also **siRNA**. (Figures 8-25a and 8-26)

mitochondrion (pl. **mitochondria**) Large organelle that is surrounded by two phospholipid bilayer membranes, contains DNA, and carries out **oxidative phosphorylation**, thereby producing most of the ATP in eukaryotic cells. (Figures 9-8 and 12-6)

mitogen Any extracellular molecule, such as a growth factor, that promotes cell proliferation.

mitosis In eukaryotic cells, the process whereby the nucleus divides, producing two genetically equivalent daughter nuclei with the diploid number of chromosomes. See also **cytokinesis** and **meiosis**. (Figure 18-34)

mitosis-promoting factor. See **MPF**.

mitotic spindle A specialized temporary structure, present in eukaryotic cells during mitosis, that captures the chromosomes and then pushes and pulls them to opposite sides of the dividing cell; also called *mitotic apparatus*. (Figure 18-36)

mobile DNA element See **transposable DNA element**.

molecular chaperone See **chaperone**.

molecular complementarity Lock-and-key kind of fit between the shapes, charges, hydrophobicity, and/or other physical properties of two molecules or portions thereof that allow formation of multiple **noncovalent interactions** between them at close range. (Figure 2-12)

molecular markers, DNA-based DNA sequences that vary among individuals (*DNA polymorphisms*) of the same species and are useful in genetic linkage studies; includes **RFLPs**.

monoclonal antibody Antibody produced by the progeny of a single B cell and thus a homogeneous protein that recognizes a single antigen (epitope). It can be produced experimentally by use of a **hybridoma**. (Figure 9-35)

monomer Any small molecule that can be linked chemically with others of the same type to form a **polymer**. Examples include amino acids, nucleotides, and monosaccharides.

monosaccharide Any simple sugar with the formula $(\text{CH}_2\text{O})_n$, where $n = 3-7$.

morphogen A signaling molecule that specifies different cell fates during development as a function of its concentration. (Figure 22-13b)

motif, structural In proteins, combination of secondary and tertiary structure that often is generated by a distinctive primary amino acid sequence; also called *structural fold*. A structural motif usually is indicative of a particular three-dimensional architecture and often is associated with a specific functional property.

motor protein Any member of a special class of mechanochemical enzymes that use energy from ATP hydrolysis to generate either linear or rotary motion; also called *molecular motor*. See also **dyneins**, **kinesins**, and **myosins**.

MPF (mitosis-promoting factor) A heterodimeric protein, composed of a **mitotic cyclin** and **cyclin-dependent kinase (CDK)**, that triggers entrance of a cell into mitosis by phosphorylating multiple specific proteins.

mRNA (messenger RNA) Any RNA that specifies the order of amino acids in a protein (i.e., the primary structure). It is produced by **transcription** of DNA by RNA polymerase. In eukaryotes, the initial RNA product (primary transcript) undergoes processing to yield functional mRNA. See also **translation**. (Figure 4-15)

mRNP-exporter A heterodimeric protein that binds to mRNA-containing ribonucleoprotein particles (mRNPs) and directs their export from the nucleus to cytoplasm by interacting transiently with **nucleoporins** in the nuclear pore complex. (Figure 8-22)

MTOC (microtubule-organizing center) General term for any structure (e.g., centrosome, spindle pole, basal body) that organizes microtubules in cells. (Figure 18-5)

multiadhesive matrix proteins Group of long flexible proteins that bind to other components of the **extracellular matrix** and to cell-surface receptors, thereby crosslinking matrix components to the cell membrane. Examples include **laminin**, a major component of the basal lamina, and **fibronectin**, present in many tissues.

multimeric For proteins, containing several polypeptide chains (or subunits).

mutagen A chemical or physical agent that induces mutations.

mutation In genetics, a permanent, heritable change in the nucleotide sequence of a chromosome, usually in a single gene; commonly causes an alteration in the function of the gene product.

myelin sheath Stacked specialized cell membrane that forms an insulating layer around vertebrate **axons** and increases the speed of impulse conduction. (Figure 23-15)

myofibril Long, slender structures within cytoplasm of muscle cells consisting of a regular repeating array of **sarcomeres** composed of thick (**myosin**) filaments and thin (**actin**) filaments. (Figure 17-29)

myosins A class of **motor proteins** that have actin-stimulated ATPase activity. Myosins move along actin **microfilaments** during muscle contraction and cytokinesis and also mediate vesicle translocation. (Figure 17-20)

NAD⁺ (nicotinamide adenine dinucleotide) A small organic molecule that functions as an electron carrier by accepting two electrons from a donor molecule and one H⁺ from the solution. (Figure 2-33a)

NADP⁺ (nicotinamide adenine dinucleotide phosphate) Phosphorylated form of NAD⁺ that is used extensively as an electron carrier in biosynthetic pathways and during photosynthesis.

Na⁺/K⁺ ATPase A P-class ATP-powered pump that couples hydrolysis of one ATP molecule to export of Na⁺ ions and import of K⁺ ions; is largely responsible for maintaining the normal intracellular concentrations of Na⁺ (low) and K⁺ (high) in animal cells; commonly called *Na⁺/K⁺ pump*. (Figure 11-12)

natural killer (NK) cells Components of the innate immune system that nonspecifically detect and kill virus-infected cells and tumor cells. (Figure 24-5)

necrosis Cell death resulting from tissue damage or other pathology; usually marked by swelling and bursting of cells with release of their contents. Contrast with **apoptosis**.

neurofilaments (NFs) A group of **intermediate filament** proteins, found only in neurons, that contribute to axonal structure and rate of transmission of action potentials down axons. (Figure 18-2b)

neuron (nerve cell) Any of the impulse-conducting cells of the nervous system. A typical neuron contains a cell body; multiple short, branched processes (**dendrites**); and one long process (**axon**). (Figures 23-1 and 23-2)

neurotransmitter Extracellular signaling molecule that is released by the presynaptic neuron at a chemical **synapse** and relays the signal to the postsynaptic cell. The response elicited by a neurotransmitter, either excitatory or inhibitory, is determined by its receptor on the postsynaptic cell. (Figures 23-19 and 23-20)

neurotrophins Family of structurally and functionally related **trophic factors** that bind to receptors called Trks and are required for survival of neurons; include nerve growth factor (NGF) and brain-derived neurotrophic factor (BDNF).

neurulation Formation of the neural tube by infolding of the neural plate, the portion of the ectoderm that develops into neural structures, in vertebrate embryos. (Figures 22-38 and 22-39)

neutrophils Phagocytic leukocytes that are attracted to sites of tissue damage and migrate into the tissue. Once activated, neutrophils secrete various chemokines, cytokines, bacteria-destroying enzymes (e.g., lysozyme), and other products that contribute to **inflammation** and help clear invading pathogens.

nicotinamide adenine dinucleotide See NAD⁺.

nicotinamide adenine dinucleotide phosphate See NADP⁺.

N-linked oligosaccharide A branched oligosaccharide chain attached to the side-chain amino group of an asparagine residue in a glycoprotein. See also **O-linked oligosaccharide**.

nociceptor Mechanosensor that responds to pain associated with injury to body tissues caused by mechanical trauma, heat, electricity, or toxic chemicals.

noncovalent interaction Any relatively weak chemical interaction that does not involve an intimate sharing of electrons. (Figures 2-6 and 2-12)

nonpolar Referring to a molecule or structure that lacks any net electric charge or asymmetric distribution of positive and negative

charges. Nonpolar molecules generally are less soluble in water than polar molecules and are often water insoluble.

Northern blotting Technique for detecting specific RNAs separated by electrophoresis by hybridization to a labeled DNA probe. See also **Southern blotting**. (Figure 5-27)

nuclear body Roughly spherical, functionally specialized region in the nucleus, containing specific proteins and RNAs; many function in the assembly of ribonucleoprotein (RNP) complexes. The most prominent type is the **nucleolus**.

nuclear envelope Double-membrane structure surrounding the nucleus; the outer membrane is continuous with the endoplasmic reticulum and the two membranes are perforated by **nuclear pore complexes**. (Figure 9-1)

nuclear lamina Fibrous network on the inner surface of the nuclear envelope composed of lamin intermediate filaments. (Figure 20-16)

nuclear pore complex (NPC) Large, multiprotein structure, composed largely of nucleoporins, that extends across the nuclear envelope. Ions and small molecules freely diffuse through NPCs; large proteins and ribonucleoprotein particles are selectively transported through NPCs with the aid of soluble proteins. (Figure 13-32)

nuclear receptor Member of a class of intracellular receptors that bind lipid-soluble molecules (e.g., steroid hormones), forming ligand-receptor complexes that activate transcription; also called *steroid receptor superfamily*. (Figure 7-50)

nucleic acid A polymer of **nucleotides** linked by **phosphodiester bonds**. DNA and RNA are the primary nucleic acids in cells.

nucleocapsid A viral **capsid** plus the enclosed nucleic acid.

nucleolus Large structure in the nucleus of eukaryotic cells where rRNA synthesis and processing occurs and ribosome subunits are assembled. (Figure 6-33a)

nucleoporins Large group of proteins that make up the **nuclear pore complex**. One class (FG-nucleoporins) participates in nuclear import and export.

nucleoside A small molecule composed of a **purine** or **pyrimidine** base linked to a pentose (either ribose or deoxyribose). (Table 2-3)

nucleosome Structural unit of **chromatin** consisting of a disk-shaped core of **histone** proteins around which a 147-bp segment of DNA is wrapped. (Figure 6-29)

nucleotide A **nucleoside** with one or more phosphate groups linked via an ester bond to the sugar moiety, generally to the 5' carbon atom. DNA and RNA are polymers of nucleotides containing deoxyribose and ribose, respectively. (Figure 2-16 and Table 2-3)

nucleus Large membrane-bounded organelle in eukaryotic cells that contains DNA organized into chromosomes; synthesis and processing of RNA and ribosome assembly occur in the nucleus.

Okazaki fragments Short (<1000 bases), single-stranded DNA fragments that are formed during synthesis of the **lagging strand** in DNA replication and are rapidly joined by DNA ligase to form a continuous DNA strand. (Figure 4-30)

oligopeptide A small to medium-sized linear polymer composed of amino acids connected by peptide bonds. The terms *peptide* and *oligopeptide* are often used interchangeably.

O-linked oligosaccharide Oligosaccharide chain that is attached to the side-chain hydroxyl group in a serine or threonine residue in a glycoprotein. See also *N-linked oligosaccharides*.

oncogene A gene whose product is involved either in transforming cells in culture or in inducing cancer in animals. Generally is a mutant form of a normal gene (**proto-oncogene**) for a protein involved in the control of cell growth or division. (Figure 25-11)

oncoprotein A protein encoded by an **oncogene** that causes abnormal cell proliferation; may be a mutant unregulated form of a normal protein, or a normal protein that is produced in excess or in the wrong time or place in an organism.

open reading frame (ORF) Region of sequenced DNA that is not interrupted by stop codons in one of the triplet reading frames. An ORF that begins with a start codon and extends for at least 100 codons has a high probability of encoding a protein.

operator Short DNA sequence in a bacterial or bacteriophage genome that binds a repressor protein and controls transcription of an adjacent gene. (Figure 7-2)

operon In bacterial DNA, a cluster of contiguous genes transcribed from one **promoter** that gives rise to an mRNA containing coding sequences for multiple proteins. (Figure 4-13a)

organelle Any membrane-limited subcellular structure found in eukaryotic cells. (Figures 1-2b and 9-1)

organ of Corti Acoustic sensory structure housed within the cochlea of the inner ear and composed of hair cells that transduce sound-generated mechanical movement into electrical impulses; the body's microphone. (Figure 23-30)

osmosis Net movement of water across a semipermeable membrane (permeable to water but not to solute) from a solution of lesser to one of greater solute concentration. (Figure 11-6)

oxidation Loss of electrons from an atom or molecule as occurs when a hydrogen atom is removed from a molecule or oxygen is added; opposite of **reduction**.

oxidation potential The voltage change when an atom or molecule loses an electron; a measure of the tendency of a molecule to lose an electron. For a given oxidation reaction, the oxidation potential has the same magnitude but opposite sign as the **reduction potential** for the reverse (reduction) reaction.

oxidative phosphorylation The phosphorylation of ADP to form ATP driven by the transfer of electrons to oxygen (O₂) in bacteria and mitochondria. Involves generation of a **proton-motive force** during electron transport and its subsequent use to power ATP synthesis.

p53 protein The product of a **tumor-suppressor gene** that plays a critical role in the arrest of cells with damaged DNA. Inactivating mutations in the *p53* gene are found in many human cancers. (Figure 25-26)

pair-rule genes In *Drosophila*, a group of genes expressed in alternating stripes along the anterior-posterior axis in the early embryo. All encode transcription factors and function, along with

gap genes and **segment-polarity genes**, in determining the body segments in flies. (Figure 22-27c)

paracrine Referring to signaling mechanism in which a target cell responds to a signaling molecule (e.g., growth factor, neurotransmitter) that is produced by a nearby cell(s) and reaches the target by diffusion.

patch clamping Technique for determining ion flow through a single ion channel or across the membrane of an entire cell by use of a micropipette whose tip is applied to a small patch of the cell membrane. (Figure 11-21)

pattern formation Process of organizing the cells, organs, and tissues of a developing embryo into well-ordered spatial patterns, like the bones of a hand or the color pattern on a butterfly wing.

P body Dense cytoplasmic domain, containing no ribosomes or translation factors, that functions in repression of translation and degradation of associated mRNAs; also called *cytoplasmic RNA-processing body*.

PCR (polymerase chain reaction) Technique for amplifying a specific DNA segment in a complex mixture by multiple cycles of DNA synthesis from short oligonucleotide primers followed by brief heat treatment to separate the complementary strands. (Figure 5-23)

pentose A five-carbon **monosaccharide**. The pentoses ribose and deoxyribose are present in RNA and DNA, respectively. (Figure 2-16)

peptide A small linear polymer composed of amino acids connected by peptide bonds. The terms *peptide* and *oligopeptide* are often used interchangeably. See also **polypeptide**.

peptide bond The covalent amide linkage between amino acids formed between the amino group of one amino acid and the carboxyl group of another with the net release of a water molecule (dehydration). (Figure 2-13)

peripheral membrane protein Any protein that associates with the cytosolic or exoplasmic face of a membrane but does not enter the hydrophobic core of the phospholipid bilayer. See also **integral membrane protein**. (Figure 10-1)

perlecan A large multidomain **proteoglycan** component of the extracellular matrix (ECM) that binds to many ECM components, cell-surface molecules, and growth factors; a major component of the **basal lamina**.

peroxisome Small organelle that contains enzymes for degrading fatty acids and amino acids by reactions that generate hydrogen peroxide, which is converted to water and oxygen by catalase.

pH A measure of the acidity or alkalinity of a solution defined as the negative logarithm of the hydrogen ion concentration in moles per liter: $\text{pH} = -\log [\text{H}^+]$. Neutrality is equivalent to a pH of 7; values below this are acidic and those above are alkaline.

phagocyte Any cell that can ingest and destroy pathogens and other particulate antigens. The primary phagocytes are neutrophils, macrophages, and dendritic cells.

phagocytosis Process by which relatively large particles (e.g., bacterial cells) are internalized by certain eukaryotic cells in a process that involves extensive remodeling of the actin cytoskeleton; distinct from **receptor-mediated endocytosis**. (Figure 9-2)

phenotype The detectable physical and physiological characteristics of a cell or organism determined by its **genotype**; also, the specific trait associated with a particular **allele**.

pheromone A signaling molecule released by an individual that can alter the behavior or gene expression of other individuals of the same species. The yeast α and a mating-type factors are well-studied examples.

phosphatase An enzyme that removes a phosphate group from a substrate by hydrolysis. Phosphoprotein phosphatases act with protein kinases to control the activity of many cellular proteins. (Figure 3-33)

phosphoanhydride bond A type of **high-energy bond** formed between two phosphate groups, such as the γ and β phosphates and the β and α phosphates in ATP. (Figure 2-31)

phosphodiester bond Chemical linkage between adjacent nucleotides in DNA and RNA; consists of two phosphoester bonds, one on the 5' side of the phosphate and another on the 3' side. (Figure 4-2)

phosphoglycerides Amphipathic derivatives of glycerol 3-phosphate that generally consist of two hydrophobic fatty acyl chains esterified to the hydroxyl groups in glycerol and a polar head group attached to the phosphate; the most abundant lipids in biomembranes. (Figures 2-20 and 10-5a)

phosphoinositides A group of membrane-bound lipids containing phosphorylated inositol derivatives; some function as **second messengers** in several signal-transduction pathways. (Figures 15-29 and 16-29)

phospholipase One of several enzymes that cleave various bonds in the hydrophilic end of **phospholipids**. (Figures 10-14)

phospholipase C (PLC) A membrane-associated phospholipase, activated by either $G_{\alpha q}$ or $G_{\alpha o}$, that cleaves the membrane lipid phosphatidylinositol 4,5-bisphosphate to generate two second messengers, DAG and IP_3 . (Figures 15-29 and 15-30)

phospholipid The major class of lipids present in biomembranes, including **phosphoglycerides** and **sphingolipids**. (Figures 10-5a, b and 2-20)

phospholipid bilayer A two-layer, sheetlike structure in which the polar head groups of phospholipids are exposed to the aqueous media on either side, and the nonpolar fatty acyl chains are in the center; the foundation for all biomembranes. (Figure 10-6a, b)

photoelectron transport Light-driven electron transport that generates a charge separation across the **thylakoid** membrane that drives subsequent events in photosynthesis. (Figure 12-33)

photorespiration A reaction pathway that competes with CO_2 fixation (**Calvin cycle**) by consuming ATP and generating CO_2 , thus reducing the efficiency of photosynthesis. (Figure 12-45)

photosynthesis Complex series of reactions occurring in some bacteria and in plant **chloroplasts** in which light energy is used to generate carbohydrates from CO_2 , usually with the consumption of H_2O and evolution of O_2 .

photosystems Multiprotein complexes, present in all photosynthetic organisms, that consist of light-harvesting complexes containing **chlorophylls** and a reaction center where **photoelectron transport** occurs. (Figure 12-42)

phragmoplast In plants, a temporary structure, formed during telophase, whose membranes become the plasma membranes of the daughter cells and whose contents develop into the new cell wall between them. (Figure 18-43)

pI See **isoelectric point**.

plakins A family of proteins that help attach **intermediate filaments** to other structures.

plaque assay Technique for determining the number of infectious viral particles in a sample by culturing a diluted sample on a layer of susceptible host cells and then counting the clear areas of lysed cells (plaques) that develop. (Figure 4-45)

plasma membrane The membrane surrounding a cell that separates the cell from its external environment; consists of a **phospholipid bilayer** and associated membrane lipids and proteins. (Figures 10-1 and 10-2)

plasmid Small, circular extrachromosomal DNA molecule capable of autonomous replication in a cell; commonly used as a **vector** in **DNA cloning**.

plasmodesmata (sing. **plasmodesma**) Tubelike cell junctions that interconnect the cytoplasms of adjacent plant cells and are functionally analogous to **gap junctions** in animal cells. (Figure 19-38)

point mutation Change of a single nucleotide in DNA, especially in a region coding for protein; can result in formation of a codon specifying a different amino acid or a stop codon. Addition or deletion of a single nucleotide will cause a shift in the **reading frame**.

polar Referring to a molecule or structure with a net electric charge or asymmetric distribution of positive and negative charges. Polar molecules are usually soluble in water.

polarity In cell biology, the presence of functional and/or structural differences in distinct regions of a cell or cellular component.

polarized In cell biology, referring to any cell or subcellular structure marked by functional and structural asymmetries.

polymer Any large molecule composed of multiple identical or similar units (**monomers**) linked by covalent bonds. (Figure 2-13)

polymerase chain reaction See **PCR**.

polypeptide Linear polymer of amino acids connected by peptide bonds, usually containing 20 or more residues. See also **protein**.

polyribosome A complex containing several **ribosomes**, all translating a single messenger RNA; also called **polysome**. (Figure 4-28)

polysaccharide Linear or branched polymer of **monosaccharides** linked by glycosidic bonds and usually containing more than 15 residues. Those with fewer than 15 residues are often called **oligosaccharides**.

polytene chromosome Enlarged chromosome composed of many parallel copies of itself formed by multiple cycles of DNA replication without chromosomal separation; found in the salivary glands and some other tissues of *Drosophila* and other dipteran insects. (Figures 6-44 and 6-45)

polyunsaturated Referring to a compound (e.g., fatty acid) in which two or more of the carbon-carbon bonds are double or triple bonds.

porins Class of trimeric transmembrane proteins through which small water-soluble molecules can cross the membrane; present in outer mitochondrial and chloroplast membranes and in the outer membrane of gram-negative bacteria (Figure 10-18)

potential energy Stored energy. In biological systems, the primary forms of potential energy are chemical bonds, concentration gradients, and electric potentials across cellular membranes.

pre-mRNA Precursor messenger RNA; the **primary transcript** and intermediates in RNA processing. (Figures 4-15 and 8-2)

pre-rRNA Large precursor ribosomal RNA that is synthesized in the nucleolus of eukaryotic cells and processed to yield three of the four RNAs present in ribosomes. (Figures 8-34 and 8-35)

primary structure In proteins, the linear arrangement (sequence) of amino acids within a polypeptide chain.

primary transcript In eukaryotes, the initial RNA product, containing **introns** and **exons**, produced by transcription of DNA. Many primary transcripts must undergo RNA processing to form the physiologically active RNA species.

primase A specialized RNA polymerase that synthesizes short stretches of RNA used as primers for DNA synthesis (Figure 4-31).

primer A short nucleic acid sequence containing a free 3'-hydroxyl group that forms **base pairs** with a complementary template strand and functions as the starting point for addition of nucleotides to copy the template strand.

probe Defined RNA or DNA fragment, radioactively or chemically labeled, that is used to detect specific nucleic acid sequences by hybridization.

programmed cell death See **apoptosis**.

prokaryotes Class of organisms, including the **bacteria** (eubacteria) and **archaea**, that lack a true membrane-limited nucleus and other organelles. See also **eukaryotes**. (Figure 1-3)

prometaphase Second stage in mitosis during which the nuclear envelope and nuclear lamina break down, and microtubules assembled from the spindle poles "capture" chromosome pairs at specialized structures called **kinetochores**. (Figure 18-34)

promoter DNA sequence that determines the site of **transcription** initiation for a RNA polymerase. (Figure 4-11)

promoter-proximal element Any regulatory sequence in eukaryotic DNA that is located within ≈ 200 base pairs of the transcription start site. Transcription of many genes is controlled by multiple promoter-proximal elements. (Figure 7-16)

prophase Earliest stage in mitosis during which the chromosomes condense, the duplicated centrosomes separate to become the spindle poles, and the mitotic spindle begins to form. (Figure 18-34)

protease Any enzyme that cleaves one or more peptide bonds in target proteins.

proteasome Large multifunctional protease complex in the cytosol that degrades intracellular proteins marked for destruction by attachment of multiple **ubiquitin** molecules. (Figure 3-29)

protein A macromolecule composed of one or more linear **polypeptide** chains and folded into a characteristic three-dimensional shape (**conformation**) in its native, biologically active state.

protein family Set of homologous proteins encoded by a **gene family**.

protein kinase A (PKA) Cytosolic enzyme that is activated by **cyclic AMP (cAMP)** and functions to phosphorylate and thus regulate the activity of numerous cellular proteins; also called **cAMP-dependent protein kinase**. (Figure 15-23)

protein kinase B (PKB) Cytosolic enzyme that is recruited to the plasma membrane by signal-induced **phosphoinositides** and subsequently activated; also called **Akt**. (Figure 16-30)

protein kinase C (PKC) Cytosolic enzyme that is recruited to the plasma membrane in response to signal-induced rise in cytosolic Ca^{2+} level and is activated by membrane-bound **diacylglycerol (DAG)**. (Figure 15-30)

proteoglycans A group of glycoproteins (e.g., perlecan and aggrecan) that contain a core protein to which is attached one or more **glycosaminoglycan (GAG)** chains. They are found in nearly all animal extracellular matrices, and some are integral membrane proteins. (Figure 19-29)

proteome The entire complement of proteins produced by a cell.

proteomics The systematic study of the amounts, modifications, interactions, localization, and functions of all or subsets of proteins at the whole-organism, tissue, cellular, and subcellular levels.

proton Common term for a hydrogen ion (H^+).

proton-motive force The energy equivalent of the proton (H^+) concentration gradient and electric potential gradient across a membrane; used to drive ATP synthesis by **ATP synthase**, transport of molecules against their concentration gradient, and movement of bacterial flagella. (Figure 12-2)

proto-oncogene A normal cellular gene that encodes a protein usually involved in regulation of cell growth or differentiation and that can be mutated into a cancer-promoting **oncogene**, either by changing the protein-coding segment or by altering its expression. (Figure 25-11)

provirus The DNA of an animal virus that is integrated into a host-cell genome; during replication of the cell, the proviral DNA is replicated and appears in both daughter cells. Activation of proviral DNA leads to production and release of progeny virions.

pseudogene DNA sequence that is similar to that of a functional gene but does not encode a functional product; probably arose by sequence drift of duplicated genes.

pulse-chase A type of experiment in which a radioactive small molecule is added to a cell for a brief period (the pulse) and then is replaced with an excess of the unlabeled form of the same small molecule (the chase). Used to detect changes in the cellular location of a molecule or its metabolic fate over time. (Figure 3-39)

pump See **ATP-powered pump**.

purines A class of nitrogenous compounds containing two fused heterocyclic rings. Two purines, adenine (A) and guanine (G), are base components of nucleotides found in DNA and RNA. See also **base pair**. (Figure 2-17)

pyrimidines A class of nitrogenous compounds containing one heterocyclic ring. Two pyrimidines, cytosine (C) and thymine (T), are base components of nucleotides found in DNA; in RNA, uracil (U) replaces thymine. See also **base pair**. (Figure 2-17)

quaternary structure The number and relative positions of the polypeptide chains in multimeric (multisubunit) proteins. (Figure 3-10b)

radioisotope Unstable form of an atom that emits radiation as it decays. Several radioisotopes are commonly used experimentally as labels in biological molecules. (Table 3-1)

Ras protein A monomeric member of the GTPase superfamily of switch proteins that is tethered to the plasma membrane by a lipid anchor and functions in intracellular signaling pathways; activated by ligand binding to **receptor tyrosine kinases** and some other cell-surface receptors. (Figures 16-20 and 16-24)

rate constant A constant that relates the concentrations of reactants to the rate of a chemical reaction.

reading frame The sequence of nucleotide triplets (**codons**) that runs from a specific translation start codon in an mRNA to a stop codon. Some mRNAs can be translated into different polypeptides by reading in two different reading frames. (Figure 4-18)

receptor Any protein that specifically binds another molecule to mediate cell–cell signaling, adhesion, endocytosis, or other cellular process. Commonly denotes a protein located in the plasma membrane, cytosol, or nucleus that binds a specific extracellular molecule (**ligand**), which often induces a conformational change in the receptor, thereby initiating a cellular response. See also **adhesion receptor** and **nuclear receptor**. (Figures 15-1 and 16-1)

receptor-mediated endocytosis Uptake of extracellular materials bound to specific cell-surface receptors by invagination of the plasma membrane to form a small membrane-bounded vesicle (early endosome). (Figure 14-29)

receptor tyrosine kinase (RTK) Member of a large class of cell-surface receptors, usually with a single transmembrane domain, including those for insulin and many growth factors. Ligand binding activates tyrosine-specific protein kinase activity in the receptor's cytosolic domain, thereby initiating intracellular signaling pathways. (Figures 16-16 and 16-17)

recessive In genetics, referring to that allele of a gene that is not expressed in the **phenotype** when the **dominant** allele is present; also refers to the phenotype of an individual (homozygote) carrying two recessive alleles. Mutations that produce recessive alleles generally result in a loss of the gene's function. (Figure 5-2)

recombinant DNA Any DNA molecule formed in vitro by joining DNA fragments from different sources.

recombination Any process in which chromosomes or DNA molecules are cleaved and the fragments are rejoined to give new combinations. Homologous recombination occurs during meiosis, giving rise to **crossing over** of homologous chromosomes. Homologous recombination and nonhomologous recombination (i.e., between chromosomes of different morphologic type) also occur during several DNA-repair mechanisms and can be carried out in vitro with purified DNA and enzymes. (Figure 5-10)

redox reaction An oxidation–reduction reaction in which one or more electrons are transferred from one reactant to another.

reduction Gain of electrons by an atom or molecule as occurs when a hydrogen atom is added to a molecule or oxygen is removed. The opposite of **oxidation**.

reduction potential (E) The voltage change when an atom or molecule gains an electron; a measure of the tendency of a molecule to gain an electron. For a given reduction reaction, E has the same magnitude but opposite sign as the **oxidation potential** for the reverse (oxidation) reaction.

release factor (RF) One of two types of nonribosomal proteins that recognize stop codons in mRNA and promote release of the completed polypeptide chain, thereby terminating **translation** (protein synthesis). (Figure 4-27)

replication fork Y-shaped region in double-stranded DNA at which the two strands are separated and replicated during DNA synthesis; also called *growing fork*. (Figure 4-30)

replication origin Unique DNA segments present in an organism's genome at which DNA replication begins. Eukaryotic chromosomes contain multiple origins, whereas bacterial chromosomes and plasmids usually contain just one.

reporter gene A gene encoding a protein that is easily assayed (e.g., β -galactosidase, luciferase). Reporter genes are used in various types of experiments to indicate activation of the promoter to which it is linked.

repressor Specific **transcription factor** that inhibits transcription.

residue General term for the repeating units in a polymer that remain after covalent linkage of the monomeric precursors.

resolution The minimum distance between two objects that can be distinguished by an optical apparatus; also called *resolving power*.

respiratory chain See **electron transport chain**.

respiratory control Dependence of mitochondrial oxidation of NADH and FADH₂ on the supply of ADP and P_i for ATP synthesis.

resting K⁺ channels Nongated K⁺ ion channels in the plasma membrane that, in conjunction with the high cytosolic K⁺ concentration produced by the Na⁺/K⁺ ATPase, are primarily responsible for generating the inside-negative resting **membrane potential** in animal cells.

restriction enzyme Any enzyme that recognizes and cleaves a specific short sequence, the *restriction site*, in double-stranded DNA molecules; used extensively to produce **recombinant DNA** in vitro; also called *restriction endonuclease*. (Figure 5-11; Table 5-1)

restriction fragment A defined DNA fragment resulting from cleavage with a particular **restriction enzyme**. These fragments are used in the production of recombinant DNA molecules and DNA cloning.

restriction fragment length polymorphisms See RFLPs.

restriction point The point in late G₁ of the cell cycle at which mammalian cells become committed to entering the S phase and completing the cycle even in the absence of growth factors; functionally equivalent to START in yeast.

retinotectal maps Corresponding maps of visual information, one in the retina created by incoming light and one in the visual part of the brain (the tectum) created by retinal ganglion cells carrying information from eye to brain. The map in the brain is like the map in the eye. (Figure 23-40)

retrotransposon Type of eukaryotic **transposable DNA element** whose movement in the genome is mediated by an RNA intermediate and involves a reverse transcription step. See also **transposon**. (Figure 6-8b)

retrovirus Type of eukaryotic virus containing an RNA genome that replicates in cells by first making a DNA copy of the RNA. This viral DNA is inserted into cellular chromosomal DNA, forming a **provirus**, and gives rise to further genomic RNA as well as the mRNAs for viral proteins. (Figure 4-49)

reverse transcriptase Enzyme found in retroviruses that catalyzes a complex reaction in which a double-stranded DNA is synthesized from a single-stranded RNA template. (Figure 6-14)

RFLPs (restriction fragment length polymorphisms) Differences among individuals in the sequence of genomic DNA that create or destroy sites recognized by particular **restriction enzymes**. Are one of several types of sequence differences between individuals that can serve as DNA-based molecular markers in human **linkage studies**. (Figure 5-36)

ribonucleic acid (RNA) See **RNA**.

ribonucleoprotein (RNP) complex General term for any complex composed of proteins and RNA. Most RNA molecules are present in the cell in the form of RNPs.

ribosome A large complex comprising several different **rRNA** molecules and more than 50 proteins, organized into a large subunit and small subunit; the engine of **translation** (protein synthesis). (Figures 4-22 and 4-23)

ribosomal RNA See **rRNA**.

ribozyme An RNA molecule with catalytic activity. Ribozymes function in RNA splicing and protein synthesis.

ribulose 1,5-bisphosphate carboxylase Enzyme located in chloroplasts that catalyzes the first reaction in the **Calvin cycle**, the addition of CO₂ to a five-carbon sugar (ribulose 1,5-bisphosphate) to form two molecules of 3-phosphoglycerate; also called *rubisco*. (Figure 12-43)

RISC See **RNA-induced silencing complex**.

RNA (ribonucleic acid) Linear, single-stranded polymer, composed of ribose **nucleotides**. mRNA, rRNA, and tRNA play different roles in protein synthesis; a variety of small RNAs play roles in controlling the stability and translation of mRNAs, and in controlling chromatin structure and transcription. (Figure 4-17)

RNA editing Unusual type of RNA processing in which the sequence of a pre-mRNA is altered.

RNA-induced silencing complex (RISC) Large multiprotein complex associated with a short single-stranded RNA (**siRNA** or **miRNA**) that mediates degradation or translational repression of a complementary or near-complementary mRNA.

RNA interference (RNAi) Functional inactivation of a specific gene by a corresponding double-stranded RNA that induces either inhibition of translation or degradation of the complementary single-stranded mRNA encoded by the gene but not that of mRNAs with a different sequence. (Figures 5-45)

RNA polymerase An enzyme that copies one strand of DNA (the *template* strand) to make the **complementary** RNA strand using as substrates ribonucleoside triphosphates. (Figure 4-11)

RNA splicing A process that results in removal of **introns** and joining of **exons** in pre-mRNAs. See also **spliceosome**. (Figures 8-8 and 8-9)

rRNA (ribosomal RNA) Any one of several large RNA molecules that are structural and functional components of **ribosomes**. Often designated by their sedimentation coefficient: 28S, 18S, 5.8S, and 5S rRNA in higher eukaryotes. (Figure 4-22)

rubisco See **ribulose 1,5-bisphosphate carboxylase**.

S (synthesis) phase See **cell cycle**.

sarcomere Repeating structural unit of striated (skeletal) muscle composed of organized, overlapping thin (**actin**) filaments and thick (**myosin**) filaments and extending from one Z disk to an adjacent one; shortens during contraction. (Figures 17-29 and 17-30)

sarcoplasmic reticulum Network of membranes in cytoplasm of a muscle cell that sequesters Ca²⁺ ions; release of stored Ca²⁺ induced by muscle stimulation triggers contraction. (Figure 17-32)

satellite DNA See **simple-sequence DNA**.

saturated Referring to a compound (e.g., fatty acid) in which all the carbon-carbon bonds are single bonds.

second messenger A small intracellular molecule (e.g., cAMP, cGMP, Ca²⁺, DAG, and IP₃) whose concentration increases (or decreases) in response to binding of an extracellular signal and that functions in **signal transduction**. (Figure 15-9)

secondary structure In proteins, local folding of a polypeptide chain into regular structures including the α helix, β sheet, and β turns.

secretory pathway Cellular pathway for synthesizing and sorting soluble and membrane proteins localized to the endoplasmic reticulum, Golgi, and lysosomes; plasma membrane proteins; and proteins eventually secreted from the cell. (Figure 14-1)

secretory vesicle Small membrane-bound vesicle derived from the **trans-Golgi network** containing molecules destined to be released from the cell.

segment-polarity genes In *Drosophila*, a group of genes encoding components of signaling systems that influence cell fates and the polarity of cytoskeletons along the anterioposterior axis in the early embryo.

segregation The process that distributes an equal complement of chromosomes to daughter cells during mitosis and meiosis.

selectins A family of **cell-adhesion molecules** that mediate Ca²⁺-dependent interactions with specific oligosaccharide moieties in glycoproteins and glycolipids on the surface of adjacent cells or in extracellular glycoproteins. (Figures 19-2 and 19-36)

shuttle vector Plasmid vector capable of propagation in two different hosts. (Figure 5-17)

side chain In amino acids, the variable substituent group attached to the **alpha (α) carbon atom** that largely determines the particular properties of each amino acid; also called *R group*. (Figure 2-14)

signaling molecule General term for any extracellular or intracellular molecule involved in mediating the response of a cell to its external environment or to other cells.

signal-recognition particle (SRP) A cytosolic ribonucleoprotein particle that binds to the ER **signal sequence** in a nascent secretory protein and delivers the nascent chain/ribosome complex to the ER membrane where synthesis of the protein and translocation into the ER are completed. (Figure 13-5)

signal sequence A relatively short amino acid sequence within a protein that directs the protein to a specific location within the cell; also called *signal peptide* and *uptake-targeting sequence*. (Table 13-1)

signal transduction Conversion of a signal from one physical or chemical form into another. In cell biology commonly refers to the sequential process initiated by binding of an extracellular signal to a receptor and culminating in one or more specific cellular responses.

silencer A sequence in eukaryotic DNA that promotes formation of condensed chromatin structures in a localized region, thereby blocking access of proteins required for transcription of genes within several hundred base pairs of the silencer; also called *silencer sequence*.

simple diffusion Net movement of a molecule across a membrane down its concentration gradient at a rate proportional to the gradient and the permeability of the membrane; also called *passive diffusion*.

simple-sequence DNA Short, tandemly repeated sequences that are found at **centromeres** and **telomeres** as well as at other chromosomal locations and are not transcribed; also called *satellite DNA*.

SINEs (short interspersed elements) Class of **retrotransposons**, 100–400 bp long, that constitute ≈ 13 percent of total human DNA. In humans, *Alu* elements account for about two-thirds of all SINEs.

siRNA A small, double-stranded RNA, 21–23 nucleotides long with two single-stranded nucleotides at each end. A single strand of the siRNA associates with several proteins to form an RNA-induced silencing complex (**RISC**) that cleaves target RNAs to which the siRNA base pairs perfectly; variously called *short* or *small interfering RNA* and *small inhibitory RNA*. siRNAs can be designed to experimentally inhibit expression of specific genes. See also **miRNA**. (Figure 8-25b)

Smads Class of transcription factors that are activated by phosphorylation following binding of members of the **transforming growth factor β (TGF β)** family of signaling molecules to their cell-surface receptors. (Figure 16-4)

SMC proteins Structural maintenance of chromosome proteins; a small family of nonhistone chromatin proteins that are critical for maintaining the morphological structure of chromosomes and their proper segregation during mitosis. Members of this family include *condensins*, which help condense chromosomes during mitosis, and *cohesins*, which link sister chromatids until their separation in anaphase. Bacterial SMC proteins function in the proper segregation of bacterial chromosomes to daughter cells. (Figure 6-38 and 20-21)

SNAREs Cytosolic and integral membrane proteins that promote fusion of vesicles with target membranes. Interaction of v-SNAREs on a vesicle with cognate t-SNAREs on a target membrane forms very stable complexes, bringing the vesicle and target membranes into close apposition. (Figure 14-10)

snoRNA (small nucleolar RNA) A type of small, stable RNA that functions in rRNA processing and base modification in the nucleolus.

snRNA (small nuclear RNA) One of several small, stable RNAs localized to the nucleus. Five snRNAs are components of the **spliceosome** and function in splicing of pre-mRNA. (Figures 8-9 and 8-11)

somatic cell Any plant or animal cell other than a **germ cell**.

somatic cell nuclear transfer (SCNT) Procedure for generating specific cell types in culture starting from embryonic or adult stem cells.

sorting signal A relatively short amino acid sequence within a protein that directs the protein to particular transport vesicles as they bud from a donor membrane in the secretory or endocytic pathway. (Table 14-2)

Southern blotting Technique for detecting specific DNA sequences separated by electrophoresis by hybridization to a labeled nucleic acid **probe**. (Figure 5-26)

Spemann organizer Signaling center on the dorsal side of early amphibian embryos that functions in anterior-posterior and dorsal-ventral patterning. (Figures 22-12 and 22-14).

SPF (S phase-promoting factor) A heterodimeric protein, composed of a **G₁ cyclin** and **cyclin-dependent kinase (CDK)**, that triggers entrance of a eukaryotic cell into the S phase of the cell cycle by phosphorylating specific proteins.

sphingolipid Major group of membrane lipids, derived from sphingosine, that contain two long hydrocarbon chains and either a phosphorylated head group (sphingomyelin) or carbohydrate head group (cerebrosides, gangliosides). (Figure 10-5b)

spliceosome Large ribonucleoprotein complex that assembles on a pre-mRNA and carries out **RNA splicing**. (Figure 8-11)

SRE-binding proteins (SREBPs) Cholesterol-dependent transcription factors, localized in the ER membrane, that are activated in response to low cellular cholesterol levels and then stimulate expression of genes encoding proteins involved in cholesterol synthesis and import as well as synthesis of other lipids. (Figure 16-38)

starch A very long, branched polysaccharide, composed exclusively of glucose units, that is the primary storage carbohydrate in plant cells. (Figure 12-28)

STAT Signal Transduction and Activation of Transcription. Class of transcription factors that are activated in the cytosol following ligand binding to **cytokine receptors**. (Figure 16-12)

steady state In cellular metabolic pathways, the condition when the rate of formation and rate of consumption of a substance are equal, so that its concentration remains constant. (Figure 2-23)

stem cell A self-renewing cell that can divide *symmetrically* to give rise to two daughter cells whose developmental potential is identical to the parental stem cell or *asymmetrically* to generate daughter cells with different developmental potentials (Figure 21-2)

stereocilia (sing. stereocilium) Nonmotile filament-filled protrusions of hair cells in the **organ of Corti** that are moved by

sound-induced vibrations, triggering depolarization in the axons associated with each hair cell. (Figures 23-30 and 23-31)

stereoisomers Two compounds with identical molecular formulas whose atoms are linked in the same order but in different spatial arrangements. In *optical isomers*, designated D and L, the atoms bonded to an **asymmetric carbon atom** are arranged in a mirror-image fashion. *Geometric isomers* include the *cis* and *trans* forms of molecules containing a double bond.

steroids A group of four-ring hydrocarbons including cholesterol and related compounds. Many important hormones (e.g., estrogen and progesterone) are steroids. *Sterols* are steroids containing one or more hydroxyl groups. (Figure 10-5c)

substrate Molecule that undergoes a change in a reaction catalyzed by an enzyme.

substrate-level phosphorylation Formation of ATP from ADP and P_i catalyzed by cytosolic enzymes in reactions that do not depend on a proton-motive force or molecular oxygen.

sulfhydryl group (–SH) A substituent group present in the amino acid cysteine and other molecules consisting of a hydrogen atom covalently bonded to a sulfur atom; also called a *thiol group*.

suppressor mutation A mutation that reverses the phenotypic effect of a second mutation. Suppressor mutations are frequently used to identify genes encoding interacting proteins. (Figure 5-9a)

symport A type of **cotransport** in which a membrane protein (*symporter*) transports two different molecules or ions across a cell membrane in the *same* direction. See also **antiport**. (Figure 11-3, [3B])

synapse Specialized region between an axon terminal of a neuron and an adjacent neuron or other excitable cell (e.g., muscle cell) across which impulses are transmitted. At a *chemical synapse*, the impulse is conducted by a **neurotransmitter**; at an *electric synapse*, impulse transmission occurs via **gap junctions** connecting the pre- and postsynaptic cells. (Figure 23-4)

syncytium A multinucleated mass of cytoplasm enclosed by a single plasma membrane.

syndecans A class of cell-surface **proteoglycans** that function in cell–matrix adhesion, interact with the cytoskeleton, and may bind external signals, thereby participating in cell–cell signaling.

synteny Occurrence of genes in the same order on a chromosome in two or more different species.

synthetic lethal mutation A mutation that increases the phenotypic effect of another mutation in the same or a related gene. (Figure 5-9b, c)

TATA box A conserved sequence in the **promoter** of many eukaryotic protein-coding genes where the transcription-initiation complex assembles. (Figure 7-12)

T cell A lymphocyte that matures in the thymus and expresses antigen-specific receptors that bind antigenic peptides complexed to **MHC molecules**. There are two major classes: *cytotoxic* T cells (CD8 surface marker, class I MHC restricted, kill virus-infected and tumor cells), and *helper* T cells (CD4 marker, class II MHC

restricted, produce cytokines, required for activation of B cells). (Figures 24-34 and 24-36)

T-cell receptor A heterodimeric antigen-binding transmembrane protein containing variable and constant regions and associated with the signal-transducing multimeric CD3 complex. (Figure 24-29)

telomere Region at each end of a eukaryotic chromosome containing multiple tandem repeats of a short telomeric (TEL) sequence. Telomeres are required for proper chromosome **segregation** and are replicated by a special process that prevents shortening of chromosomes during DNA replication. (Figure 6-49)

telophase Final mitotic stage during which the nuclear envelope re-forms around the two sets of separated chromosomes, the chromosomes decondense, and division of the cytoplasm (cytokinesis) is completed. (Figure 18-34)

temperature-sensitive (ts) mutation A mutation that produces a wild-type phenotype at one temperature (the permissive temperature) but a mutant phenotype at another temperature (the nonpermissive temperature). This type of mutation is especially useful in identification of genes essential for life. (Figure 5-6)

tertiary structure In proteins, overall three-dimensional form of a polypeptide chain, which is stabilized by multiple noncovalent interactions between side chains. (Figure 3-10a)

thylakoids Flattened membranous sacs in a chloroplast that can be arranged in stacks and contain the photosynthetic pigments and **photosystems**. (Figure 12-29)

tight junction A type of cell–cell junction between the plasma membranes of adjacent epithelial cells that prevents diffusion of macromolecules and many small molecules and ions in the spaces between cells and diffusion of membrane components between the apical and basolateral regions of the plasma membrane. (Figure 19-15)

Toll-like receptor (TLR) Member of a class of cell-surface and intracellular receptors that recognize a variety of microbial products. Ligand binding initiates a signaling pathway that induces various responses depending on the cell type. (Figure 24-35)

topogenic sequences Segments within a protein whose sequence, number, and arrangement direct the insertion and orientation of various classes of transmembrane proteins into the endoplasmic reticulum membrane. (Figure 13-13)

transcription Process in which one strand of a DNA molecule is used as a template for synthesis of a **complementary RNA** by RNA polymerase. (Figures 4-10 and 4-11)

transcription-control region Collective term for all the DNA regulatory sequences that regulate transcription of a particular gene.

transcription factor (TF) General term for any protein, other than RNA polymerase, required to initiate or regulate transcription in eukaryotic cells. *General* factors, required for transcription of all genes, participate in formation of the transcription-preinitiation complex near the start site. *Specific* factors stimulate (**activators**) or inhibit (**repressors**) transcription of particular genes by binding to their regulatory sequences.

transcription unit A region in DNA, bounded by an initiation (start) site and termination site, that is transcribed into a single **primary transcript**.

transcytosis Mechanism for transporting certain substances across an epithelial sheet that combines **receptor-mediated endocytosis** and **exocytosis**. (Figures 14-25 and 24-10)

transfection Experimental introduction of foreign DNA into cells in culture, usually followed by expression of genes in the introduced DNA. (Figure 5-32)

transfer RNA See **tRNA**.

transformation (1) Permanent, heritable alteration in a cell resulting from the uptake and incorporation of a foreign DNA into the host-cell genome; also called *stable transfection*. (2) Conversion of a “normal” mammalian cell into a cell with cancer-like properties usually induced by treatment with a virus or other cancer-causing agent.

transforming growth factor beta (TGF β) A family of secreted signaling proteins that are used in the development of most tissues in most or all animals. Members of the TGF β family more often inhibit growth than stimulate it. Mutations in TGF β signal-transduction components are implicated in human cancer, including breast cancer. (Figures 16-3 and 16-4)

transgene A cloned gene that is introduced and stably incorporated into a plant or animal and is passed on to successive generations.

transgenic Referring to any plant or animal carrying a **transgene**.

trans-Golgi network (TGN) Complex network of membranes and vesicles that serves as a major branch point in the **secretory pathway**. Vesicles budding from this most-distal Golgi compartment carry membrane and soluble proteins to the cell surface or to lysosomes. (Figures 14-1 and 14-17)

transition state State of the reactants during a chemical reaction when the system is at its highest energy level; also called the *transition state intermediate*.

translation The **ribosome**-mediated assembly of a polypeptide whose amino acid sequence is specified by the nucleotide sequence in an mRNA. (Figure 4-17)

translocon Multiprotein complex in the membrane of the rough endoplasmic reticulum through which a nascent secretory protein enters the ER lumen as it is being synthesized. (Figure 13-7)

transmembrane protein See **integral membrane protein**.

transport protein See **membrane transport protein**.

transport vesicle A small membrane-bounded compartment that carries soluble and membrane “cargo” proteins in the forward or reverse direction in the **secretory pathway**. Vesicles form by budding off from the donor organelle and release their contents by fusion with the target membrane.

transposable DNA element Any DNA sequence that is not present in the same chromosomal location in all individuals of a species and can move to a new position by **transposition**; also called *mobile DNA element* and *interspersed repeat*. (Table 6-1)

transposition Movement of a **transposable DNA element** within the genome; occurs by a cut-and-paste mechanism or copy-and-paste mechanism depending on the type of element. (Figure 6-8)

transposon, DNA A **transposable DNA element** present in prokaryotes and eukaryotes that moves in the genome by a mech-

anism involving DNA synthesis and transposition. See also **retrotransposon**. (Figures 6-9 and 6-10)

triacylglycerol See **triglyceride**.

triglyceride Major form in which fatty acids are stored and transported in animals; consists of three fatty acyl chains esterified to a glycerol molecule. (p. 491)

tRNA (transfer RNA) A group of small RNA molecules that function as amino acid donors during protein synthesis. Each tRNA becomes covalently linked to a particular amino acid, forming an **aminoacyl-tRNA**. (Figures 4-19 and 4-20)

trophic factor Any of numerous signaling proteins required for the survival of cells in multicellular organisms; in the absence of such signals, cells often undergo “suicide” by **apoptosis**.

tubulin A family of globular cytoskeletal proteins that polymerize to form the cylindrical wall of **microtubules**. (Figure 18-3)

tumor A mass of cells, generally derived from a single cell, that arises due to loss of the normal regulators of cell growth; may be **benign** or **malignant**.

tumor-suppressor gene Any gene whose encoded protein directly or indirectly inhibits progression through the cell cycle and in which a loss-of-function mutation is oncogenic. Inheritance of a single mutant allele of many tumor-suppressor genes (e.g., *RB*, *APC*, and *BRCA1*) greatly increases the risk for developing colorectal and other types of cancer. (Figures 25-9 and 25-11)

ubiquitin A small protein that can be covalently linked to other intracellular proteins, thereby tagging these proteins for degradation by the **proteasome**, sorting to the lysosome, or alteration in the function of the target protein. (Figure 3-29)

uncoupler Any natural substance (e.g., the protein thermogenin) or chemical agent (e.g., 2,4-dinitrophenol) that dissipates the **proton-motive force** across the inner mitochondrial membrane or thylakoid membrane of chloroplasts, thereby inhibiting ATP synthesis.

uniporter A type of transport in which a membrane protein (*uniporter*) mediates movement of a small molecule across a membrane down its concentration gradient via **facilitated transport**. The glucose transporters (**GLUT proteins**) are well-studied examples of uniporters. (Figure 11-3, [3A])

unsaturated Referring to a compound (e.g., fatty acid) in which one of the carbon-carbon bonds is a double or triple bond.

upstream (1) For a gene, the direction opposite to that in which RNA polymerase moves during transcription. Nucleotides upstream from the +1 position (the first transcribed nucleotide) are designated -1, -2, etc. (2) Events that occur earlier in a cascade of steps (e.g., signaling pathway). See also **downstream**.

upstream activating sequence (UAS) Any protein-binding regulatory sequence in the DNA of yeast and other simple eukaryotes that is necessary for maximal gene expression; equivalent to an enhancer or promoter-proximal element in higher eukaryotes. (Figure 7-16)

vaccine An innocuous preparation derived from a pathogen and designed to elicit an immune response in order to provide immu-

nity against a future challenge by a virulent form of the same pathogen.

van der Waals interaction A weak **noncovalent interaction** due to small, transient asymmetric electron distributions around atoms (dipoles). (Figure 2-10)

vector In cell biology, an autonomously replicating genetic element used to carry a cDNA or fragment of genomic DNA into a host cell for the purpose of gene cloning. Commonly used vectors are bacterial plasmids and modified bacteriophage genomes. See also **expression vector** and **shuttle vector**. (Figure 5-13)

viral envelope A phospholipid bilayer forming the outer covering of some viruses (e.g., influenza and rabies viruses); is derived by budding from a host-cell membrane and contains virus-encoded glycoproteins. (Figure 4-47)

virion An individual viral particle.

virus A small intracellular parasite, consisting of nucleic acid (RNA or DNA) enclosed in a protein coat, that can replicate only in a susceptible host cell; widely used in cell biology research. (Figure 4-44)

V_{\max} Parameter that describes the maximal velocity of an enzyme-catalyzed reaction or other process such as protein-mediated transport of molecules across a membrane. (Figures 3-22 and 11-4)

Western blotting Technique in which proteins separated by electrophoresis are attached to a nitrocellulose or other membrane, and specific proteins then are detected by use of labeled antibodies; also called *immunoblotting*. (Figure 3-38)

wild type Normal, nonmutant form of a gene, protein, cell, or organism.

Wnt A family of secreted signaling proteins used in the development of most tissues in most or all animals. Mutations in Wnt signal-transduction components are implicated in human cancer, especially colon cancer. Receptors are Frizzled-class proteins with seven transmembrane segments. (Figure 16-32)

x-ray crystallography Commonly used technique for determining the three-dimensional structure of macromolecules (particularly proteins and nucleic acids) by passing x-rays through a crystal of the purified molecules and analyzing the diffraction pattern of discrete spots that results. (Figure 3-42)

zinc finger Several related DNA-binding **structural motifs** composed of secondary structures folded around a zinc ion; present in numerous eukaryotic transcription factors. (Figures 3-9b and 7-25)

zygote A fertilized egg; diploid cell resulting from fusion of a male and female **gamete**.

- Epidermal growth factor (EGF), 626, 680
 in cancer, 706
 in heart disease, 706
 in Ras/MAP signaling, 693–694
 receptor tyrosine kinases and, 680–682, 681f, 682f

- Epidermal growth factor domain, 71–72, 71f
 Epidermal growth factor receptors, 680–681, 681f
 Epidermal stem cells, 914–915, 915f
 Epidermolysis bullosa, 795–796, 795f, 810
 Epidermolysis congenita, 795–796, 795f, 810
 Epifluorescence microscopy, 380f
 Epigenetic inheritance, 303
 Epigenetic processes, 254
 Epimerases, 45
 Epinephrine, 10
 in glycogenolysis, 648–649
 receptors for, 636–637, 636f
 desensitization of, 651
 structure of, 1020f
 Epithelial cell(s)
 apical membrane in, 471, 471f
 apical surface of, 399, 471, 808, 809, 809f, 810f
 basal lamina of, 808
 basal surface of, 399, 808, 809, 809f, 810f
 basolateral-apical sorting in, 605, 605f
 basolateral membrane in, 471, 471f
 basolateral surface of, 471, 808, 809f
 cell-cell adhesion/cell-matrix adhesion in, 808–819. *See also* Cell-cell adhesion; Cell-matrix adhesion
 culture of, 399–400, 401f
 development of, 960
 functions of, 713, 808
 intestinal, 470–471, 471f
 lateral surface of, 399, 808, 809, 809f, 810f
 membrane transport in, 470–472, 471f, 472f
 polarized, 471, 808
 structure of, 808, 809f
 Epithelial cell junctions, 372, 399–400, 471, 471f, 802f, 803, 809–819, 810f
 Epithelial growth factor, in breast cancer, 631
 Epithelial-mesenchymal transitions, 812–813, 813f, 960
 Epithelial tissue, 801, 802
 Epithelium, 399, 802
 basal lamina of, 399, 401f
 definition of, 713
 development of, 951
 extracellular matrix of, 816–817, 820–825
 paracellular transport in, 815–816, 816f
 simple columnar, 808, 809f
 simple squamous, 808, 809f
 stratified squamous, 808, 809f
 transcellular transport in, 471, 471f, 814, 816f
 transitional, 808, 809f
 types of, 808, 809f
 Epitope tagging, 98, 198, 385
 Epitopes, 78, 198, 401, 1068
 Epo receptor. *See* Erythropoietin (Epo) receptor

orphan, 660
overview of, 635
structure of, 635–636, 636f, 666f
in taste perception, 1036
in transcription, 697–702
types of, 639, 640t
- G protein-coupled receptor/cAMP pathway,
646–652
adenylyl cyclase binding and activation in,
646–647, 646f, 647f
anchoring proteins in, 652, 652f
cellular responses in, 649, 650t
desensitization in, 651–652, 651f
down-regulation in, 651–652, 651f
in glycogen metabolism, 648–650, 648f,
649f
protein kinase C activation in, 647–649
signal amplification in, 650–651, 650f
- G protein-coupled receptor/IP₃ pathway,
Ca²⁺/calmodulin complex in, 655–656
- G protein-coupled receptor/IP₃/DAG pathway,
653–657, 654f, 655f
- G₀ phase, 18f, 848f, 849, 850f. *See also* Cell
cycle
in mammals, 881–882
in yeast, 877, 877f
- G₁ cyclins, 850, 850f
in mammals, 881, 882f
in yeast, 874–878, 874f–877f
inhibition of, 895
- G₁ phase, 18, 18f, 848, 848f, 849, 850f. *See*
also Cell cycle
arrest of, by DNA damage, 1136–1137,
1137f
changes in, in cancer, 1134, 1136–1137,
1137f
regulation of, 872–879
- G₂ phase, 18, 18f, 781, 848f, 849. *See also*
Cell cycle
changes in, in cancer, 1134
in mammals, 881, 882f
in yeast, 877, 877f
- G_α, 90, 91f
- GABA (gamma-aminobutyric acid), structure
of, 1020f
- Gag protein, 614, 615f
- G_α-GDP complex, 637–638, 638f, 644
- G_α-GTP complex, 637–638, 638f, 641,
643–644, 643f
in GPCR/adenylyl cyclase pathway, 646–652
- Gain-of-function mutations, 167
in cancer, 1119–1121
- GAL1 promoter, 206
- GAL4 transcription factor, 288–289, 289f
- Galactose, 45, 45f, 46f
membrane transport of, 443
- GalT protein, in fertilization, 957
- Gametes, 19, 167, 950
parental type, 175
recombinant type, 175
- Gametogenesis, 953–955
genomic imprinting in, 958
- Gamma-aminobutyric acid (GABA), structure
of, 1020f
- Gamma carboxylation, of amino acids, 43
- Gamma-secretase, 705–706, 705f
- Gamma-tubulin, 761, 762
- Gamma-tubulin ring complex, 761, 762
- γ light chains, 1065. *See also*
